Neuroblastomas are, by definition, Schwannian stroma-poor (<50% of the tumor tissue) and can be subtyped as undifferentiated, poorly differentiated (<5% of tumor cells have features of differentiation), or differentiating (>5% of tumor cells show differentiation toward ganglion cells). Additional factors that contribute to the prognostic distinction of stroma-poor, neuroblastic tumors (neuroblastoma) as favorable or unfavorable subtypes include the MKI, which is defined as the number of tumor cells undergoing mitosis or karyorrhexis per 5000 neuroblastic cells (i.e., low MKI, <100 cells; intermediate, 100–200 cells; high, >200 cells) and the patient's age (<1.5 years, 1.5–5 years, >5 years). It has been hypothesized that neuroblastic cells with maturational potential require an in vivo latent period before demonstrating histologic evidence of differentiation; therefore, there is a certain allowance for mitotic and karyorrhectic activities of neuroblastic cells in tumors in infants and younger children.[33] Thus, newborns with neuroblastoma are very likely to have favorable histology disease.

Evidence for spontaneous regression of a subgroup of neuroblastoma comes from the observation that small nodules of primitive neuroblasts are routinely found in the developing adrenal gland and even during the early postnatal period. Beckwith and Perrin[34] first described these microscopic nodules that they termed "neuroblastoma in situ" in the adrenals of infants undergoing autopsy following death from non-malignancy-related causes. The incidence of this finding was more than 200-fold greater than the clinical incidence of neuroblastoma, suggesting that perhaps many neuroblastomas spontaneously regress or mature into lesions that never become clinically apparent. Even clinically apparent neuroblastoma can regress or spontaneously mature. Although initially thought to be mediated by the immune system, this may be the result of the withdrawal of neurotrophic maintenance factors such as nerve growth factor. Neuroblastoma probably represents failure of this process of regression.

Staging

International Neuroblastoma Staging System. Current staging of neuroblastoma is based on the International Neuroblastoma Staging System (INSS) (Table 91.2).[35] The INSS is a surgical–pathologic staging system that takes into account several variables, including the following: completeness of resection of primary tumor, ipsilateral and contralateral involvement of lymph nodes, and tumor location in relation to the midline. Complete evaluation for metastatic disease must also be undertaken for accurate staging, although newborns have a lower incidence of disseminated disease at presentation than children (35% vs. 60%), with bone metastases, in particular, rarely occurring in newborns.

Stage distribution varies significantly with age. Patients older than 30 days present more often with stage 4 disease (45%), whereas less than 20% of patients present with stage 1 disease. This stage distribution is notably different in neonates: more than 30% present with stage 1 disease, and only 10% present with stage 4 disease (another 25% have 4S disease). Of patients with 4S disease, more than 20% are younger than 30 days of age at diagnosis.

Table 91.2 International neuroblastoma staging system

1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with primary tumor may be positive).
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline,[a] with or without regional lymph node involvement; localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
4	Any primary tumor with dissemination to distant lymph nodes, bone marrow, bone, liver, skin, and/or other organs (except as defined for stage 4S).
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and/or bone marrow[b] (limited to infants <1 year of age).

[a] The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

[b] Marrow involvement in stage 4S should be minimal, that is, <10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate. More extensive marrow involvement would be considered to be stage 4. The MIBG scan (if performed) should be negative in the marrow.

International Neuroblastoma Risk Group Staging System (INRGSS). In an effort to stage patients prior to any therapy and to avoid influences of differences in surgical approach and aggressiveness, the International Neuroblastoma Risk Group (INRG) task force developed a staging system based strictly on imaging at presentation and "image-defined risk factors" (IDRFs). This staging system was initially developed to enable comparison of risk-based clinical trials worldwide and allow for staging on the basis of tumor imaging and not the extent of surgical resection. These IDRFs (Table 91.3) were first proposed by the European International Society of Pediatric Oncology Neuroblastoma Group and generally reflect the presence of encasement of major vessels or nerves, or the infiltration of adjacent organs/structures by a locoregional tumor. Localized tumors are classified as either L1 (absence of any IDRFs) or L2 (the presence of 1 or more of 20 IDRFs). Cecchetto et al. reported in 2005 that the presence of one or more of these image-defined surgical risk factors was associated with a lower complete resection rate and a greater risk of surgery-related complications when attempting an initial resection of a localized neuroblastoma.[36] The designation of a localized tumor as L2 at presentation is not meant to suggest that all of these tumors need to receive neoadjuvant therapy, however. Additionally, Yoneda et al.[37] recently reported that only 27% of tumors with one or more IDRFs (L2) became negative for IDRFs (L1) after neoadjuvant chemotherapy.

Stratification for risk of recurrence

As previously mentioned, one of the notable characteristics of neuroblastoma is the substantial heterogeneity of the disease. Increasing evidence indicates that the biologic and molecular features of neuroblastoma are highly predictive of clinical behavior. Current treatment is based on risk stratification that takes into account both clinical and biologic variables predictive of disease relapse. The most important clinical variables appear to be age and stage at diagnosis. The most powerful biologic factors at this time appear to be *MYCN* status,[11,12] ploidy[38] (for infants), and histopathologic classification.[39] However, additional biologic and molecular variables continue to be evaluated, and two, the allelic status at chromosomes 1p36 and 11q23 are currently being used to define the duration of therapy for certain patients. Taken together, these variables currently define the Children's Oncology Group (COG) risk stratification (Table 91.4), with children being categorized into three risk groups predictive of relapse; low, intermediate, and high risk. The probability of prolonged disease-free survival for patients in each group is >95%, >90%, and <30%, respectively. Treatment is intensified depending on the patient's increased risk of disease relapse. However, it is important to note that although low- and intermediate-risk patients account for approximately 36% and 21%, respectively, of patients of all ages, neonatal patients present with low- and intermediate-risk disease in 58% and 40% of cases, respectively; rarely do they have high-risk disease. In particular, only 3% of all patients with stage 1 or 2 neuroblastoma have *MYCN* amplification, with the incidence in newborns being even lower.[40]

MANAGEMENT

Risk-based therapy

Low-Risk Disease. The treatment for patients with low-risk disease has generally been surgical resection alone, even in the presence of microscopic residual disease (stage 1), gross residual disease (stage 2A), or gross residual disease with ipsilateral lymph node involvement (stage 2B), if the tumor is without *MYCN* amplification. Infants with stage 4S disease who are not experiencing substantial symptoms may undergo an initial biopsy and observation only, if the tumor has favorable biologic factors. Infants with a localized adrenal mass who meet certain imaging and biochemical criteria may also be observed.

Intermediate-Risk Disease. Patients receive cycles of cyclophosphamide, doxorubicin, carboplatin, and etoposide, given

Table 91.3 Objective surgical risk factors for primary resection of localized neuroblastoma

1. **Neck:**
   a. Tumor encasing major vessel(s) (e.g., carotid artery, vertebral artery, internal jugular vein)
   b. Tumor extending to base of skull
   c. Tumor compressing the trachea
   d. Tumor encasing the brachial plexus
2. **Thorax:**
   a. Tumor encasing major vessel(s) (e.g., subclavian vessels, aorta, superior vena cava)
   b. Tumor compressing the trachea or principal bronchi
   c. Lower mediastinal tumor, infiltrating the costovertebral junction between T9 and T12 (may involve the artery of Adamkiewicz supplying the lower spinal cord)
3. **Abdomen:**
   a. Tumor infiltrating the porta hepatis and/or the hepatoduodenal ligament
   b. Tumor encasing the origin of the celiac axis, and/or the superior mesenteric artery
   c. Tumor invading one or both renal pedicles
   d. Tumor encasing the aorta and/or vena cava
   e. Tumor encasing the iliac vessels
   f. Pelvic tumor crossing the sciatic notch
4. **Dumbbell tumors with symptoms of spinal cord compression:** any location
5. **Infiltration of adjacent organs/structures:** diaphragm, kidney, liver, duodenopancreatic block, and mesentery

Source: Cecchetto G. et al., Surgical risk factors in primary surgery for localized neuroblastoma: The LNESG1 study of the European International Society of Pediatric Oncology Neuroblastoma Group, *J Clin Oncol*, 2005;23:8483–8489.

every 3 weeks. The duration of therapy (i.e., the number of cycles) will depend upon which of three intermediate risk groups a patient is placed in, with group stratification again being based on clinical and biologic risk factors (Table 91.4). One of these biologic factors will include loss of heterozygosity (LOH—loss of one of two normally paired chromosomal regions) at chromosome 1p or 11q (unbalanced), as these events have been shown to be independently associated with decreased progression-free survival in patients with low- and intermediate-risk disease.[14]

The overall surgical goal in intermediate-risk patients is to perform the most complete tumor resection possible, consistent with preservation of full organ and neurologic function. This may necessitate leaving residual disease adherent to critical anatomic structures. It is no longer required that infants with 4S disease undergo resection of their primary tumor. In addition, if these infants are too unstable at presentation, it is no longer required that they even undergo an initial biopsy.

High-Risk Disease. This group accounts for less than 2% of neonatal neuroblastomas and comprises cases where the tumor is *MYCN* amplified. Although the incidence of high-risk neuroblastoma in neonates is much lower than that for patients older than 30 days (incidence >45%), neonates with high-risk disease have a 2-year overall survival (OS) of only 30% despite tolerating the treatment regimen.[41]

The general approach to treating patients with high-risk neuroblastoma includes intensive induction chemotherapy, myeloablative consolidation therapy with stem cell rescue, radiation therapy, and immunotherapy for minimal residual disease. The role of surgery for control of locoregional disease is controversial. Several reports have suggested that patients with INSS stage 3 or 4 disease who undergo gross total resection of their primary tumor and locoregional disease experience improved local tumor control and increased overall survival[42–44]; however, other reports have not confirmed these observations.[45,46] Despite the uncertainty of the role of surgery, the COG high-risk protocol currently recommends attempting gross total resection of the primary tumor and locoregional disease in patients with high-risk neuroblastoma.

Surgical management

Preoperative Preparation. All patients, prior to surgery, should have a complete blood count, chemistry panel (to include liver function tests if the liver is involved), and a coagulation screen. Urinary catecholamines and serum ferritin and LDH should already have been obtained as part of the initial workup. Blood pressure should be normalized with pharmacologic means if hypertension was present at presentation. Operations on neuroblastoma are often hazardous, and hemorrhage is a frequent complication; hence, packed red blood cells should be available for transfusion during or immediately after the operation.

Operative Approach (Open). Tumor size, the extent of vascular encasement, and exact tumor location should be considered in selecting the approach for a retroperitoneal neuroblastoma. Options available for the abdominal incision include a transverse incision, bilateral subcostal (Chevron) incisions, or a midline incision (Figure 91.1). A transthoracic (intercostal), transdiaphragmatic extension can be added for resection of neuroblastomas with either thoracoabdominal extension or extensive periaortic or celiac axis encasement. The tumor should be carefully exposed to determine the relation between the tumor and

Table 91.4 Children's oncology group risk stratification for children with neuroblastoma

Risk stratification	INSS stage	Age	Biology
Low			
Group 1			
	1	Any	Any
	2A/2B (>50% resected)	Any	*MYCN*-NA, any histology/ploidy
	4S	<365 days	*MYCN*-NA, FH, DI > 1
Intermediate			
Group 2			
	2A/2B (<50% resected or Bx only)	0–12 years	*MYCN*-NA, any histology/ploidy[a]
	3	<365 days	*MYCN*-NA, FH, DI > 1[a]
	3	≥365 days to 12 years	*MYCN*-NA, FH[a]
	4S (symptomatic)	<365 days	*MYCN*-NA, FH, DI > 1[a]
Group 3			
	3	<365 days	*MYCN*-NA, either UH or DI = 1[a]
	4	<365 days	*MYCN*-NA, FH, DI > 1[a]
	4S	<365 days	*MYCN*-NA, either UH or DI = 1[a]; or unknown biology
Group 4			
	4	<365 days	*MYCN*-NA, either DI = 1 or UH
	3	365 to <547 days	*MYCN*-NA, UH, any ploidy
	4	365 to <547 days	*MYCN*-NA, FH, DI > 1
High			
	2A/2B, 3, 4, 4S	Any	*MYCN* amplified, any histology/ploidy
	3	>547 days	*MYCN*-NA, UH, any ploidy
	4	365 to >547 days	*MYCN*-NA, UH or DI = 1
	4	>547 days	Any

Note: DI, DNA index; FH, favorable histology; *MYCN*-NA, *MYCN* not amplified; UH, unfavorable histology.

[a] If tumor contains chromosomal 1p LOH or unb11qLOH, or if data are missing, treatment assignment is upgraded to next group.

normal organs and vessels. If encasement of major vessels such as the aorta, vena cava, or their branches is found, tumor dissection must be performed to free the vessels completely. With deliberate dissection of the tumor from the mesenteric and renal vessels, injury to the liver, bowel, spleen, and kidneys can be avoided (Figure 91.2), although this frequently results in piecemeal division and excision of the tumor.[46] For a more detailed description of extensive surgical resection of neuroblastoma, see the work of Kiely.[46]

Operative Approach (Laparoscopic). Laparoscopic adrenalectomy is feasible in children and may have some benefits (less pain, shorter hospitalization, improved cosmesis) compared to open adrenalectomy. Laparoscopy may be a reasonable approach in neuroblastoma, in particular, where negative margins, piecemeal removal of the specimen, and leaving residual tumor are not usually of concern. In addition, vascular encasement, characteristic of high-risk neuroblastoma in older children, does not usually occur in newborns, making a minimally invasive approach feasible. However, an appropriate oncologic procedure, which currently still includes bilateral lymph node sampling for staging, is required. The surgeon also should consider that, as discussed previously, small adrenal masses discovered in the perinatal period and 4S neuroblastomas may not need to be removed.

Transperitoneal laparoscopic adrenalectomy is generally performed with the operative side up but in such a fashion that allows rapid transition to an open procedure, if that becomes necessary. The table is tilted into reverse Trendelenburg position and can be flexed to increase the distance between the costal margin and the iliac crest. Generally, four ports are used (Figure 91.3). Dissection is

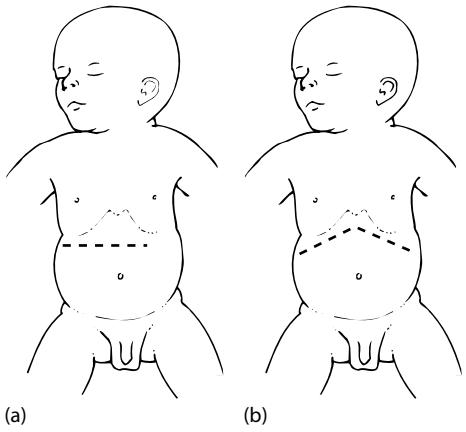

Figure 91.1 Incisions for retroperitoneal neuroblastoma resection. **(a)** Transverse abdominal incision (right-sided tumor). **(b)** Bilateral subcostal incision.

performed in much the same manner as the open procedure, with care being taken to secure the adrenal vein and to avoid the renal vessels. Bilateral retroperitoneal lymph node sampling is technically required for appropriate neuroblastoma staging although rarely done.

SPECIAL CONSIDERATIONS IN INFANTS

The best management for neuroblastoma in infants continues to be evaluated in clinical trials because of the very heterogeneous behavior of the disease and the fact that many of these tumors will follow a very benign clinical course without any therapeutic intervention, including surgery. This is an important consideration given the potential toxicities and long-term complications of adjuvant chemotherapy and radiation therapy, which include organ dysfunction and second malignancies.[47] Because extensive

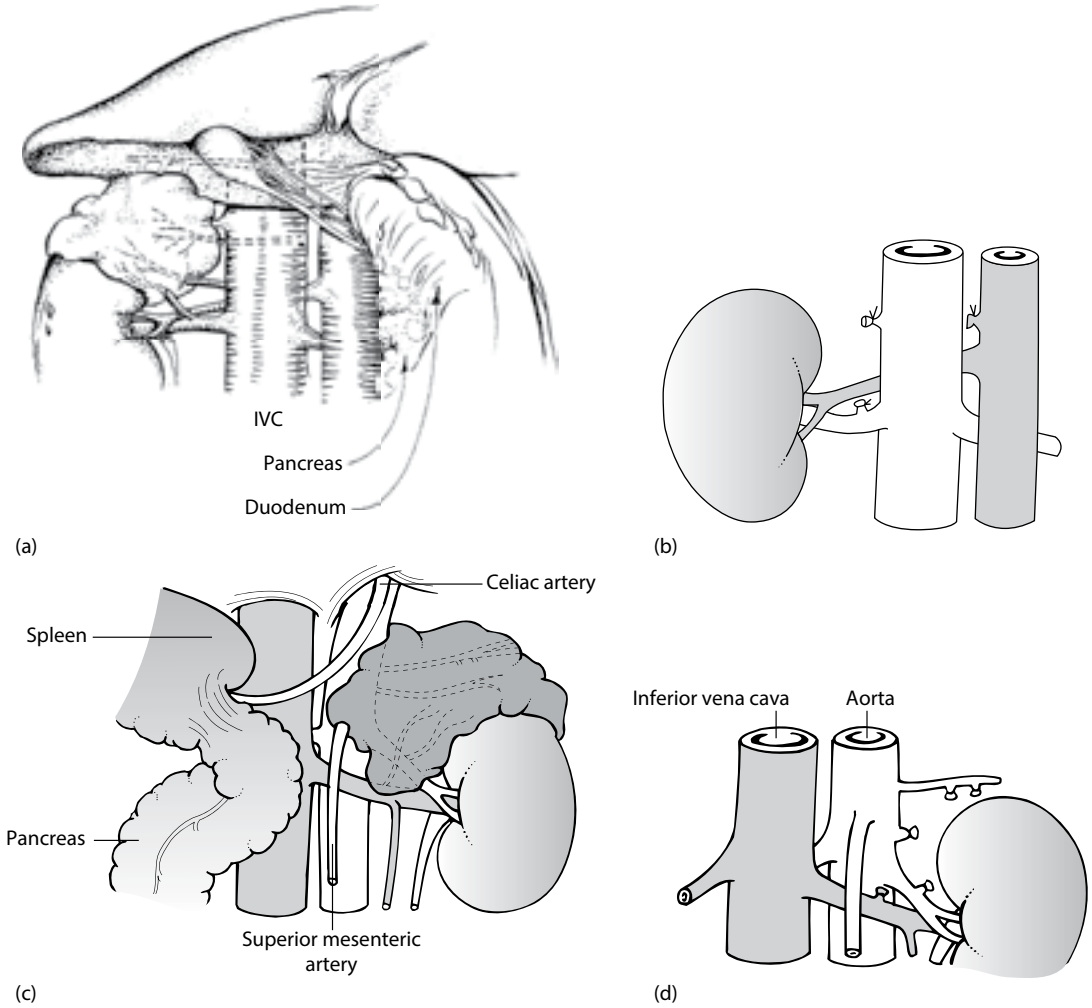

Figure 91.2 Right adrenal tumor. **(a)** The duodenum and head of the pancreas with important structures in the lesser omentum mobilized to the left. The renal vessels are dissected out, and branches to the tumor are divided. Medially, the tumor is juxtaposed to the inferior vena cava (IVC), and sharp dissection may be needed to separate it. At least one vein will need to be secured and divided. **(b)** The tumor has been removed. Left adrenal tumor. **(c)** The lienorenal ligament has been divided, allowing mobilization of the spleen and pancreas to the right. The renal vessels are visible and dissected out—branches to the tumor are divided. Next the tumor is dissected from the aorta dividing any vessels. **(d)** Tumor has been removed and the vascular supply divided.

surgery is often required, intraoperative and postoperative complications are also not uncommon.[48,49] As many as 80% of patients will experience significant blood loss during surgery. Up to 10% will suffer an injury to a major vascular structure (aorta, vena cava, or renal vessels), and injury to other viscera (bowel, liver, spleen, or kidney) occurs in approximately 5% of cases. As with all surgical procedures, there is also a risk for anesthetic complications, with infants being at higher risk. The overall mortality for young infants undergoing adrenal surgery for tumor resection may be as high as 2%.[50] Postoperative complications have a wide range. Wound complications occur in 1%–5% of cases, as does postoperative bowel obstruction. In addition, hypertension, chylous ascites, pleural effusion, infection and sepsis, diarrhea, kidney loss, and prolonged total parenteral nutrition (TPN) requirement can occur. Because of these potential therapy-related complications in neonatal patients, efforts have been directed toward reducing the treatment.

Expectant Observation of Localized Neuroblastoma. A prospective COG study, ANBL00P2, led by Nuchtern and colleagues,[51] evaluated observation alone in infants 6 months of age or younger on the date an adrenal mass was first identified that was 16 mL or less in volume if solid or 65 mL or less in volume if the mass was at least 25% cystic and did not cross the midline. Additionally, disease had to be limited to the adrenal gland as determined by adjunct imaging (e.g., MIBG, CT, or MRI scans) and bone marrow biopsy. However, parents also had the option to choose upfront surgical resection for their child. Follow-up investigations included measurement of urinary catecholamine levels and serial abdominal ultrasound studies in addition to occasional CT or MRI scans. Infants with an increase of 50% in tumor volume or an increase in catecholamine levels were referred for surgery. Of the 87 patients in this study, 83 (95.4%) were enrolled in the observation arm, of whom 56 completed the observation. A total of 20 (23.0%) patients underwent resection: 4 immediately on enrollment into the surgery arm and 16 who were originally enrolled in the observation arm. The 3-year event-free survival for patients with small adrenal masses was 97.7%, and the 3-year OS at a median follow-up of 3.2 years was 100%. Of the 83 patients in the observation arm, 67 (81%) were spared surgery. These patients were observed without biopsy for definitive histologic diagnosis. Interestingly, however, one case has subsequently been reported detailing a patient initially observed expectantly on this protocol who, 4 years later, developed high-risk stage 4 *MYCN*-amplified neuroblastoma.[52]

Hero et al.[53] reported the German experience observing 93 infants with non-*MYCN*-amplified, localized, unresected stage 2 or 3 neuroblastoma. Forty-four (47.3%) tumors exhibited regression, 35 (37.6%) progressed locally or to stage 4S, and 4 (4.3%) progressed to stage 4, requiring high-risk therapy. Of these 35 patients, 22 received chemotherapy for tumor progression or lack of regression. Strikingly, of the 93 patients, 21 with stage 3 disease were initially observed, of whom 11 (52.4%) showed tumor regression. The entire cohort had an excellent 3-year OS of 99%. These data provide support for a trial of observation in patients with INSS stage 2 or stage 3 disease with favorable biology.

In July 2014, the COG opened a phase III study, ANBL1232 (NCT02176967), with the aim of further reducing therapy by assessing a response- and biology-based treatment approach of observation in two cohorts: infants younger than 12 months with INRG stage L1 tumors smaller than 5 cm (group A) and non-high-risk patients younger than 18 months with INRG stage L2 tumors with favorable histologic and genomic features (group B). This study will expand on ANBL00P2 findings by increasing the age cutoff for avoiding surgery from 6 months, increasing the tumor size from 3.1 cm to 5 cm, and allowing nonadrenal primaries to be observed. Patients in group A may have nonadrenal tumors confirmed by either an MIBG scan or elevated levels of catecholamine metabolites and may be observed up to 96 weeks without a biopsy. If these patients show disease progression, then surgical resection is recommended. Patients in group B must be asymptomatic and must have a diagnostic biopsy to confirm favorable biology. If these patients show a more than 25% increase in tumor volume, they will undergo two cycles of chemotherapy or surgical resection. If after initial therapy, the patients have a partial response or better, observation will be continued. Of note, this is an ongoing prospective study, so the management recommendations are not fully validated and confirmed.

Stage 4S Neuroblastoma. In 1971, D'Angio, Evans, and Koop[54] reported a number of patients with a special variant of metastatic neuroblastoma, termed IVS (now referred to as 4S [INSS] or 4M [INRGSS]). These patients were infants who typically had a single, small primary tumor but who often had extensive metastatic disease in the liver, resulting in significant hepatomegaly, skin nodules, and small

amounts of disease in the bone marrow (<10% of the mononuclear cells). If there was more extensive bone marrow involvement or bone metastasis, then the disease was categorized as stage 4. They noted that these patients with 4S neuroblastoma were quite remarkable, because the large amount of disease generally underwent spontaneous regression, even without treatment, and the infants ultimately had no evidence of disease.

Gigliotti et al. reported that 45 (33.6%) of 134 neonates with neuroblastoma presented with stage 4S disease. Data from the COG suggests an incidence of 25% for neonates, which is in sharp contrast to an incidence of less than 5% in patients older than 30 days.[55] Supportive therapy only has been recommended for this stage of neuroblastoma because of the high incidence of spontaneous regression and the resultant good prognosis.[56] Most of these patients have tumor with favorable biology (single-copy *MYCN*, favorable Shimada histology, and DNA index >1); therefore, they are assigned to the low-risk classification and receive no therapy. However, despite the generally benign course of their malignancy, these infants can die of complications caused by the initial bulk of their disease. Limited chemotherapy, local irradiation, or minimal resection can be used to treat infants with life-threatening symptoms of hepatomegaly. Operative placement of a Silastic pouch as a temporary abdominal wall may be a choice for those with significant liver enlargement that causes either respiratory compromise secondary to diaphragmatic elevation or obstruction of the inferior vena cava. This procedure may help to avoid life-threatening events until shrinkage of the liver is achieved by either spontaneous regression or therapy. The rare infant with 4S disease and either unfavorable Shimada histology or a DNA index of 1 (or whose biology is not known) will be treated for intermediate-risk disease (group 3), and those with 4S disease that is *MYCN* amplified will be treated for high-risk disease.

Patients with 4S disease are also being studied prospectively on the ANBL1232 protocol. Children younger than 18 months who are asymptomatic and have tumors with favorable biology are being observed. If patients are symptomatic, then age is considered as the next criterion: patients younger than 3 months receive immediate chemotherapy (with full staging within 1 month) with plans to perform a tumor biopsy when they are stable, whereas patients 3–18 months old undergo a tumor biopsy and proceed through a response-based algorithm to determine the length of treatment. ANBL1232 will also prospectively study an objective scoring system in which values will be assigned to symptoms and laboratory results to generate a clinical score. The trial will evaluate gastrointestinal symptoms, respiratory compromise, venous return, renal compromise, and hepatic dysfunction.

Screening for Neuroblastoma. Because the two most important clinical variables for predicting outcome in patients with neuroblastoma are tumor stage and patient age at the time of diagnosis, it was hypothesized that earlier detection of neuroblastoma through mass population screening might significantly impact neuroblastoma-associated mortality. In Japan in the 1980s, mass screening of neuroblastoma was performed in infants by quantitating urinary VMA and HVA; initially, the mass screening showed very encouraging results.[57] However, subsequent population-based studies with concurrent control groups performed in Germany and North America found that although the incidence of neuroblastoma increased, the additional cases were largely early-stage, favorable biology, low-risk tumors.[47] Because the overall mortality of patients with neuroblastoma was not affected, the implication of these studies was that mass screening most likely detected tumors that would have undergone spontaneous regression and not been detected clinically. Thus, there currently appears to be no role for screening infants for neuroblastoma. A recent follow-up study by Ioka et al.[58] confirmed that the cessation of mass screening for neuroblastoma in Japan did not appear to increase mortality due to neuroblastoma or the incidence of advanced stage disease in older children.

Soft-tissue sarcoma

MARTIN T. CORBALLY

INTRODUCTION

Soft-tissue sarcoma is a rare tumor in children and is considerably rarer still in the newborn period (birth to 6 weeks). Their behavior is, for the most part, benign with malignant varieties accounting for no more than 2% of all sarcomatous lesions in childhood. The very rarity of these tumors and their generally benign behavior underscore the need for a careful and balanced approach to their management. This is further emphasized by the complexity of surgery, radiotherapy, and chemotherapy in this age group, which, when weighed against the potential lifelong complications of therapy, justifies careful and measured discussion as to the most appropriate course of action.

Immature newborn metabolism, renal function, and unpredictable drug toxicity make chemotherapy complex and difficult to administer in the newborn period. In all situations where neoadjuvant or adjuvant therapy is considered appropriate, it must take into account age-dependent physiology, immature neural, and gonadal development. Certain tumors may exhibit alarming histopathological features but yet behave in a nonaggressive manner. Radical and mutilating surgery and/or toxic neoadjuvant treatment in this clinical context is clearly not indicated. However, even tumors that act in a benign manner and display no worrying histology or clinical behavior may present some cause for concern by virtue of their location such as a neck infantile fibrosarcoma (CIFS) and airway obstruction, or a perineal IFS and its potential for urinary obstruction.

From a biological perspective, it must also always be noted that certain neonatal "malignant tumors" such as neuroblastoma are subject to immunological influences that ultimately result in their spontaneous resolution. Spontaneous resolution of congenital infantile fibrosarcoma has been previously reported, and a watch-and-wait approach may be considered in some very young patients when strict observation is guaranteed. Inconsistent lack of histological correlation with clinical behavior and the known immunomodulation of some tumors therefore render the treatment options more complex and require careful discussion. Any individual center's experience of this condition may be limited and underscores the need for greater multicenter collaboration and prospective studies.

This chapter will discuss soft-tissue sarcoma in the newborn period, which strictly extends from birth to 6 weeks of age. However, most reports and series recognize the extreme rarity of this condition and usually include patients up to 2 or 3 years.

GENETICS

Although multifactorial elements are felt to contribute to the development of malignant tumors, the majority have a genetic component. Single gene mutations and more complex constitutional chromosomal anomalies favor the development of neonatal neoplasms. Some are well known, if not for the early development of neoplasia, but more for its late arrival, e.g., Down syndrome and leukemia, hepatoblastoma or rhabdomyosarcoma in Li–Fraumeni syndrome, Wilms tumor, and Denys–Drash syndrome. More recently, some reports have confirmed the association of the ETV6–NTRK3 fusion gene in more than 87% of infantile fibrosarcomas. This T chromosomal translocation is not completely specific to sarcomas, however, and has been noted in some leukemias and mesoblastic nephromas.

Soft-tissue sarcomas, however, are a heterogenous group of tumors derived from mesenchymal cells and may therefore differentiate into muscle, fibrous, and other structures. As such, they may present in many locations and with a variety of symptoms. Despite being rare, it is, however, an important diagnosis to consider in any infant presenting with an unusual mass or obstruction, or prolapse of a mass from the vagina, urethra, or other orifice.

Soft-tissue sarcomas account for approximately 10% of all neonatal tumors and only 2% of all childhood sarcomas. In general, they fall into three different groups:

1. Congenital (infantile) fibrosarcoma (CIFS)
2. Rhabdomyosarcoma (RMS)
3. Non-rhabdomyosarcoma soft-tissue sarcoma (non-RMS)

OVERVIEW OF MANAGEMENT

In general, treatment is tailored to the individual patient but should, if possible, be with a curative intent while limiting the toxicity of therapy and avoiding morbidity or mutilating surgery (Figure 92.1). Mutilating surgery is only rarely required and in exceptional and life-threatening circumstances. This is the principle mainstay of treatment. Management decisions are often complex and require discussion in a multidisciplinary forum composed of pediatric surgical oncologists, oncologists, radiotherapists, histopathologists, and nursing. While chemosensitivity and the response to radiotherapy (if utilized) vary from patient to patient, chemotherapy is modified to minimize the severity of immunosuppression and serious infection. Radiotherapy is occasionally required, but it is generally held only as a treatment of last resort with greater emphasis being placed on surgical resection where possible.

All patients need histological diagnosis either by open, tru-cut, or fine-needle aspiration cytology (FNAC). Whatever the biopsy type, it is essential that it is taken by the pediatric surgical oncologist who is ultimately responsible for the surgical care of the patient. An inappropriately sited biopsy may ultimately compromise the subsequent surgical approach and make complete tumor clearance difficult or impossible. Essentially the needle tract or open biopsy tract must be in the line of the ultimate incision for surgical clearance. The biopsy should be sufficient to allow accurate and complete diagnosis and is sent fresh to the laboratory for histology and appropriate histochemistry and biological studies. The biopsy, where possible, should minimize tumor spillage, and this may be aided by the generous use of chlorhexidine sponges, argon, or standard diathermy.

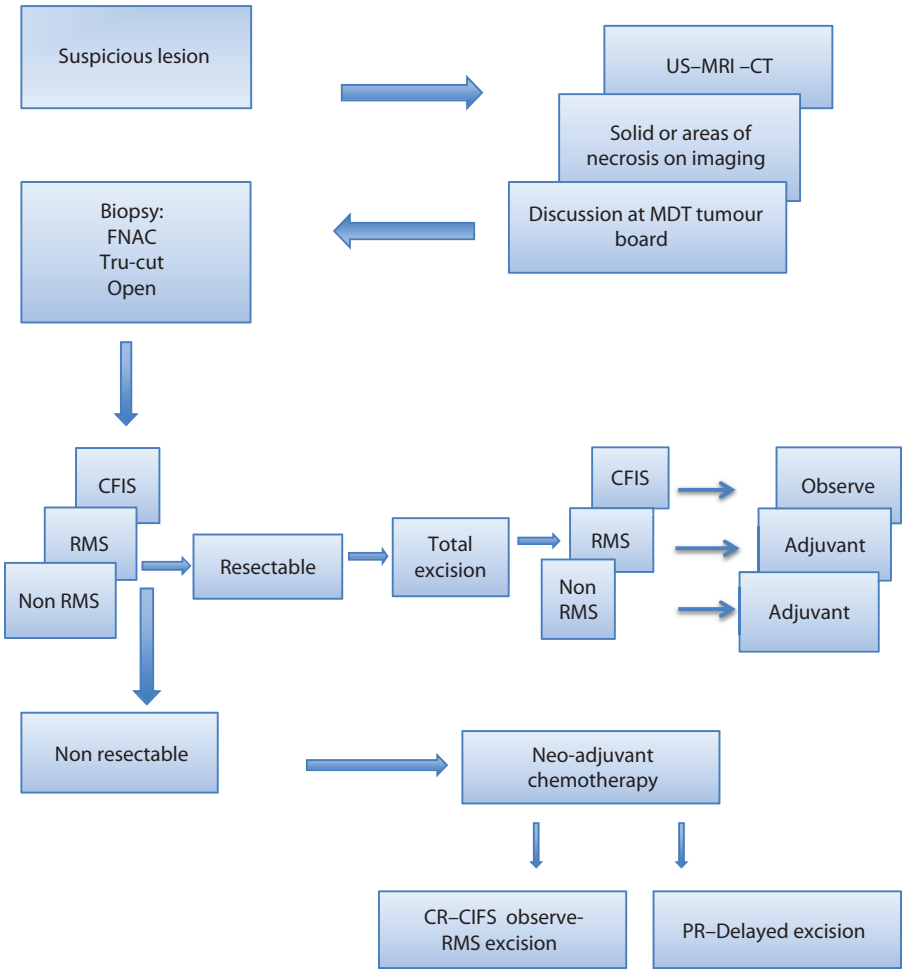

Figure 92.1 Algorithm of management.

At presentation, it is important not just to determine histology but also to accurately stage the tumor. This will include a variety of imaging, such as ultrasound, CT, and MRI. These may or may not require sedation or anesthesia to minimize movement. A PET CT may also be useful in determining stage and response to treatment and can aid the postoperative evaluation of surgical sites. In addition, a bone marrow sample is taken to determine metastatic involvement. Pleural effusions may be tapped or chest drains inserted as necessary.

Generally localized soft-tissue sarcomas are best treated by wide local excision where this does not interfere with growth or function and is not of itself mutilating. Limited surgical resection (debulking) may be the only appropriate option when complete excision is not possible or mutilating. Complete clearance can be planned after chemotherapy (see below) has reduced the tumor to a more manageable dimension.

If complete surgical excision is considered possible and nonmutilating, then representative nodal sampling should also be performed to facilitate complete surgical staging. This is also important since histological appearances may not always correlate with biological behavior. Primary excision should aim to achieve negative clear margins both clinically and histologically, and residual margins indicate the need for re-excision or adjuvant therapy in RMS but not always in CIFS. A reasonable margin of 2 cm in an en bloc excision is adequate to ensure that capsular invasion does not compromise the completeness of the surgical margin. On occasions, frozen section can help confirm negative margins or direct further excision.

CHEMOTHERAPY

The sensitivity of the young patient to the potential side effects of chemotherapy is well documented and indicates the need for treatment in a pediatric oncology center. In general, neoadjuvant therapy is indicated when the tumor is unresectable and where such an approach would interfere with function and would of itself be mutilating. Experience has shown that the majority of initially inoperable tumors are rendered operable by such therapy. Furthermore, over a third of patients treated with neoadjuvant chemotherapy for inoperable CIFS sustain a complete response with no clinical or radiological evidence of disease and do not require further surgery.

Clearly, anthracyclines and alkylating agents are associated with a significant risk of cardiac and gonadal/mutagenic complications, respectively, in the very young patient. The combination of vincristine and actinomycin D (VA regimen), while not without its own potential complications, is as effective as VAC (added cyclophosphamide), and evidence suggests that this is the safest and most effective regime in the young patient with IFS. Three-year event-free survival in the European Pediatric Soft Tissue Sarcoma Study group is currently 84%, with an overall survival of 94% over a mean follow-up of 4.7 years.

SPECIFIC TUMORS

Infantile fibrosarcoma (CIFS)

There are two main types of fibrosarcoma that share similar histological appearances but different clinical behavior: congenital and adult types (Figure 92.2).

CIFS is a well-recognized tumor with a very low tendency to metastasize. CIFS is the commonest soft-part sarcoma in children under 1 year of age and as such is regarded as of intermediate malignancy. Presentation is usually as a mass and initial rapid growth. It is more common on the extremities and in males, and is commonly an antenatal diagnosis. Although metastatic spread is uncommon, local recurrence may occur in as many as 45% following attempts at curative excision/resection. It is generally a chemosensitive tumor, but surgery remains the mainstay of treatment. The relative frequency of local recurrence and occasional advanced disease has often warranted more radical initial surgery or considerations for neoadjuvant chemotherapy. Microscopic disease after surgery does not always indicate the need for further therapy, and a watch-and-wait policy is generally the first therapeutic option.

The adult type generally occurs in older children and is indistinguishable from the CIFS type but is differentiated by its clinical behavior.

Rhabdomyosarcoma

RMS is an extremely rare tumor in the neonatal period, and of 3217 patients reported by the Intergroup Rhabdomyosarcoma Study, only 14 were in this age group. Arising from mesenchymal tissue, it has a strong tendency toward myogenesis and can spread to nodes, lung, and liver. It is associated with the Li–Fraumeni syndrome and type 1 neurofibromatosis (Figure 92.3).

There are two main histological subtypes: embryonal and alveolar with distinct clinical outcomes and chromosomal

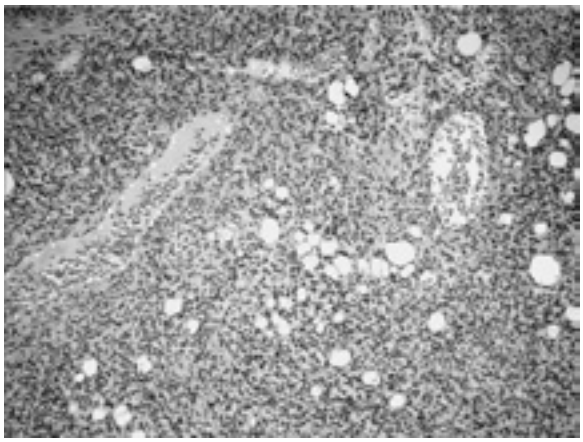

Figure 92.2 Congenital fibrosarcoma. Spindle cell proliferation infiltrating fat (adipocytes are the white blob-like cells) showing "blood lakes" characteristic of this entity.

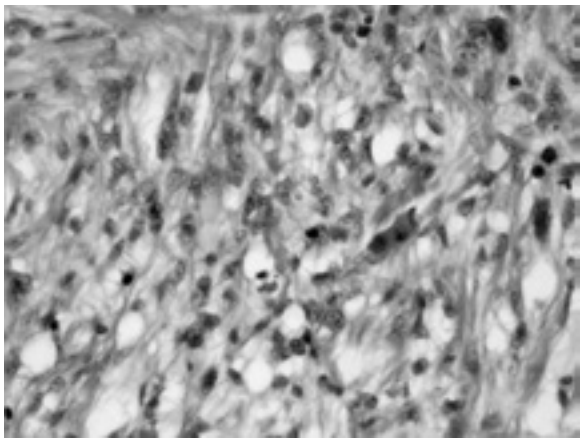

Figure 92.3 Embryonal rhabdomyosarcoma. Spindle cell sarcoma with elongated strap-like cytoplasmic processes and hyperchromatic nuclei showing considerable pleomorphism. The intensely eosinophilic cytoplasm is characteristic of skeletal muscular differentiation.

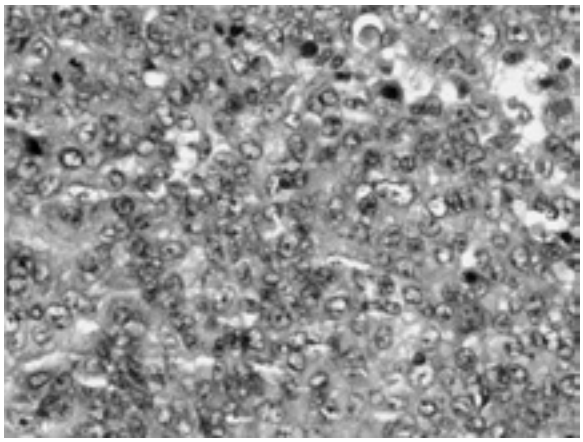

Figure 92.4 Rhabdoid sarcoma. The tumor cells are round with abundant eosinophilic cytoplasm and contain large, vesicular nuclei with prominent micronucleoli. Multiple mitotic figures are evident in the field imaged. The cytoplasm classically shows condensation of intermediate filaments, as seen here, which produces the "rhabdoid" phenotype.

translocations. Embryonal sarcoma is associated with the allelic loss of the 11p15 region and is marked histologically by degrees of myogenic differentiation that express desmin and muscle-specific actin. However, the most specific immunohistochemical markers are MyoD, Myogenin, and Vimentin.

While RMS can occur at any site, they are most common in the head and neck and genitourinary areas. Approximately 50% of RMS arises in the bladder, vagina, testicular (paratesticular), and sacrococcygeal sites, and 50% have already metastasized at presentation. Prognosis depends on histology, stage, and also site as head and neck presentations have better than 90% survival. Survival in neonates is approximately 50% with necrosis and small round cell configuration associated with a poor prognosis.

Treatment is aimed at complete surgical resection, and this may also include neoadjuvant and adjuvant chemotherapy, the latter indicated even if macroscopic clearance has been achieved. Radiotherapy is reserved for loss of local control.

Aggressive surgical management is not indicated in the presence of nonsterilized metastasis or if such an approach was extremely mutilating or associated with significant functional morbidity.

Non-rhabdomyosarcoma soft-tissue sarcoma

These comprise an extremely rare group of neonatal sarcomas such as malignant mesenchymal sarcoma, primitive sarcoma, angiosarcoma, and rhabdoid sarcoma. They tend to arise on the trunk, extremities, and head and neck area, and as such may be confused with IFS and RMS. Presenting as a painless mass, they exhibit marked clinical, histological, and biological heterogeneity (Figure 92.4).

Their management parallels that of both IFS and RMS with a need for accurate histology and planned treatment. Wide local excision is usually sufficient as less than 10% have metastatic disease at presentation. The response to chemotherapy is less predictable, and consideration may have to be given to radiotherapy.

SUMMARY

Soft-tissue sarcoma is a rare tumor in childhood and infancy, and its management is made complex by the lack of consistency between histology and clinical behavior. Management must be tailored to the individual patient and on the basis of consensus discussion at an MDT Tumour Board. It is important to differentiate rhabdomyosarcoma from congenital infantile fibrosarcoma. In general, the aim is curative excision, but where this is not possible or considered mutilating (functionally or anatomically), then neoadjuvant chemotherapy with vincristine and actinomycin D (avoiding cyclophosphamide) is offered. Residual tumor is excised, but complete clinical and radiological remission (CIFS) can be observed without surgery. Microscopic CIFS after surgery may be observed, but RMS must be treated further. Very young patients may also be closely observed, since as many as 35% of IFS may undergo spontaneous resolution. The rarity of this tumor and the complexity of management indicate the need for multicenter prospective database and collaboration.

Hepatic tumors

BENJAMIN A. FARBER, WILLIAM J. HAMMOND, AND MICHAEL P. LA QUAGLIA

INTRODUCTION

Benign and malignant liver tumors in infants comprise 4%–5% of all neoplasms in the fetus and neonate, and are being detected perinatally with increasing frequency through ultrasound.[1,2] The spectrum of these pathological masses in newborns and infants is different from that found in older children (see Table 93.1). With advances in the understanding of the biology of these tumors over the past decades, approach to their treatment has also evolved. While most hepatic tumors are metastatic rather than primary, this chapter aims to describe the current and evolving approaches to the management of the most common benign and malignant primary liver tumors occurring in newborns (see Figure 93.1).

BENIGN LIVER TUMORS

Hepatic infantile hemangiomas

Hepatic vascular tumors are the most common benign pediatric tumor, affecting 4%–5% of white infants.[3] The true incidence is likely higher, as a large percentage of these lesions are asymptomatic and usually detected incidentally. The term hemangioma has often been indiscriminately used for vascular lesions. Generally speaking, there are two types of hemangiomas: infantile and congenital.

Infantile hemangiomas (IHs) are benign endothelial cell neoplasms characterized by proliferation of normal or abnormal blood vessels. While most infantile and congenital hemangiomas are cutaneous, liver lesions are fairly common.[4] Both visceral and cutaneous hemangiomas exhibit similar biologic behavior. Despite a landmark paper by Mulliken and Glowacki[5] that grouped vascular birthmarks into two major categories—hemangiomas and malformations—clinicians and pathologists do not agree about the descriptions of vascular lesions in the liver, using the term IH interchangeably and inclusively for true hemangiomas, arteriovenous malformations, and hemangioendothelioma.

TUMOR BIOLOGY

IHs are associated with white race, female gender, prematurity, low birth weight, and multiple gestations. The exact pathogenesis of IH remains unknown. It is thought to arise from a defect in endothelial or progenitor cells. The classification is made based on their depth of soft tissue involvement: superficial, deep, and mixed. Typically, superficial defects appear 1–4 weeks after birth, and deep lesions tend to develop between 2 and 3 months of age. There is additional differentiation for hepatic hemangiomas (HHs) and with regard to focal, multifocal, or diffuse forms of the disease. Most HHs are clinically insignificant and involute entirely without alteration of the hepatic parenchyma.

It is believed that HHs are the equivalent counterpart to rapidly involuting congenital hemangiomas (RICHs) and that they are fully formed at birth and involute faster than typical IHs. HHs can be detected on prenatal imaging, and there may be transient anemia and thrombocytopenia, but these are self-limited phenomena. They characteristically have a rapid proliferation of capillaries in the first year of life (proliferative phase), followed by a gradual, inevitable regression of the tumor over 1 to 5 years (involuting phase) and continual improvement until resolution and replacement of the tumor with fibrofatty tissue (involuted phase). Histologically, in the proliferative phase, endothelial hyperplasia with incorporation of H-thymidine and large numbers of mast cells can be observed.[6] This phase is defined by a high expression of proliferating cell nuclear antigen, type IV collagenase, and vascular endothelial growth factor (VEGF). High expression of tissue inhibitor of metalloproteinase (TIMP-1), an inhibitor of new blood vessel formation, is found exclusively in the involuting phase.[7] In contrast, vascular malformations do not express any of these biological markers or show signs of spontaneous regression and, instead, continue to grow with the child.

Glucose transporter 1 (GLUT1) immunoreactivity is found in IHs and distinguishes them from other subgroups of solitary liver hemangiomas, such as RICH, partially involuting congenital hemangiomas (PICHs), and non-involuting congenital

Table 93.1 Primary pediatric liver tumors

Age group	Malignant	Benign
Infants, toddlers	Hepatoblastoma (43%)	Hemangioma (14%)
	Rhabdoid tumors (<1%)	Mesenchymal hamartoma (6%)
	Malignant germ cell tumors (<1%)	Teratoma (<1%)
School age/adolescents	HCC and transitional cell tumors (23%)	Hepatic adenomas (2%)
	Sarcomas (7%)	Focal nodular hyperplasia (2%)

hemangiomas (NICHs). It is of note that vascular malformations do not express GLUT1.[8,9]

CLASSIFICATION

Hepatic IHs have been widely referred to as hemangioendotheliomas and divided into types 1 and 2. However, this term is misleading, as their behavior is different from epithelioid hemangioendotheliomas (with metastatic potential) and Kaposiform hemangioendotheliomas (KHEs; associated with the Kasabach–Merritt phenomenon [KMP][10]), both of which are true neoplasms that do not spontaneously regress.

The International Society for the Study of Vascular Anomalies (ISSVA) settled that cutaneous vascular tumors should be classified into two categories: hemangiomas (GLUT1-positive) and a heterogenous group of anomalies represented by vascular malformations (GLUT1-negative).[5,10] Drawing parallels from this, Mo et al.[9] have suggested two groups for hepatic vascular tumors: hepatic IHs (GLUT1-positive and typically multiple, but may be focal) and hepatic vascular malformations with capillary proliferation (GLUT1-negative, solitary masses).

Christison-Lagay et al.[3] and Dickie et al.[11] have proposed classifying hemangiomas based on imaging characteristics. Three types of lesions have been described: focal, multifocal, and diffuse (see Figure 93.2a–c). Focal lesions are solitary and are usually GLUT1-negative. Multifocal lesions are discrete hypodense lesions with intervening normal hepatic parenchyma. Diffuse HHs present with extensive hepatic involvement and near-total replacement of the hepatic parenchyma with innumerable lesions. Both multifocal and diffuse lesions are GLUT1-positive. Some authors have proposed that a subgroup of GLUT1-indeterminate or negative solitary hepatic vascular tumors may exhibit behavior and immunohistochemical characteristics similar to those of the RICH.[3,12,13] Table 93.2 presents the currently accepted ISSVA classification for vascular anomalies.

CLINICAL PRESENTATION

Multifocal and diffuse HHs are true IHs both by histopathology and natural history. There is a spectrum of disease with multifocal HHs randomly distributed among otherwise normal liver parenchyma and diffuse HHs exhibiting near-total liver parenchyma replacement. The diagnosis is often made while screening for visceral hemangioma based upon finding of multiple cutaneous IHs. Massive hepatomegaly from multifocal HHs can result in abdominal compartment syndrome and respiratory failure. All HHs express type III iodothyronine deiodinase and can inactivate thyroid hormone giving rise to profound hypothyroidism, resulting in exacerbation of cardiac failure and cognitive delay.

Clinical presentations of the various lesions described above overlap considerably. Infantile HHs are frequently associated with cutaneous hemangiomas, the incidence of liver lesions being higher with multiple or large skin lesions.[4] Most liver hemangiomas may be clinically silent and escape detection. Some, however, remain asymptomatic and are discovered on routine prenatal or postnatal imaging performed for unrelated reasons. The most common presenting features are an abdominal mass, hepatomegaly, and anemia. Patients with large tumors can be critically ill at presentation with congestive heart failure (CHF), inferior vena cava compression, respiratory distress, and even abdominal compartment syndrome and multiorgan failure. Hypothyroidism, which may be present due to type III iodothyronine deiodinase activity by the liver hemangioma, may contribute to the CHF. It is more common in the diffuse type, but has been noted in multifocal and large solitary hemangiomas. Screening with thyroid function tests at presentation is, therefore, advisable. Rarely, hemorrhagic shock with or without disseminated intravascular coagulation may follow a rupture of the lesion. Rupture can be precipitated by percutaneous needle biopsy.

INVESTIGATIONS

No serum marker is clinically useful for diagnosis, though elevations in alpha-fetoprotein (AFP) have been reported.[14–16] These elevations are usually mild and call into question the importance of differentiating larger lesions from hepatoblastoma (HB).

Hepatic IHs are generally diagnosed using computed tomography (CT) and magnetic resonance imaging (MRI) with contrast enhancement. These lesions are hypodense on CT scanning with centripetal (outside-in) enhancement. On MRI, they are hypointense on T1 and hyperintense on T2-weighted sequences. Imaging criteria used in the diagnosis include nodular peripheral enhancement followed by centripetal fill-in, change to isodensity on CT, or isointensity on MRI with the blood vessels and a complete fill-in in the late phase on contrast-enhanced images.

Contrast-enhanced ultrasonography (CEUS) is being increasingly used as the first-line imaging modality in the characterization of liver lesions.[17,18] The nodular peripheral enhancement expanding centrally is also seen with CEUS. This may offer a diagnostic advantage over CT and MRI in view of the low rate of adverse reactions from the microbubble contrast, allowing for multiple injections and assessments and its use in patients with decreased renal function.[18–20]

Angiography has been declining as a diagnostic modality in vascular anomalies of the liver. Endovascular modalities are now used to outline the vasculature of tumors in a subgroup of infants who present with high-output cardiac failure for whom a high-flow shunt amenable to embolization is suspected.

Hepatic IHs must be distinguished from epithelioid hemangioendothelioma, an intermediate-grade neoplasm that has the potential to metastasize. This is a tumor seen mostly in adults and rarely in older children.[21–23] It has not been reported in newborns. It consists of multifocal and confluent masses of homogenous liver nodules with peripheral enhancement. Treatment usually involves liver resection or transplantation.

MANAGEMENT

Asymptomatic focal lesions do not need treatment and may be followed with serial ultrasound examinations until resolution. This can be every 1 to 2 months until the lesion is stable, after which scans can be performed two to three times a year until involution is demonstrated. If there are signs of asymptomatic shunts, a closer follow-up schedule can be implemented. Multifocal lesions have a similar natural history to that of focal lesions and can be similarly observed. Propranolol is the pharmacologic treatment of choice for symptomatic multifocal and diffuse HH with cardiac failure, abdominal distention, or hypothyroidism. The mechanism of propranolol is to hasten tumor involution, reducing cardiac failure and hypothyroidism. Embolization may be required for lesions with large arteriovenous shunts resulting in heart failure. Infants with HH should be followed with serial abdominal imaging until the hemangioma has involuted. If the diagnosis is unclear, a percutaneous needle biopsy may be necessary to rule out malignancy.[24] Diffuse liver lesions are the most difficult subgroup to manage. In addition to the above, an early consultation with the transplant team should be considered for patients whose disease progresses despite medical management.

Table 93.2 2014 ISSVA classification of vascular anomalies

Vascular tumors	Vascular malformations
Benign vascular tumors	*Simple vascular malformations*
Infantile hemangioma	Capillary malformations
Congenital hemangioma (RICH, NICH, and PICH)	Lymphatic malformations
Tufted angioma	Venous malformations
Spindle-cell hemangioma	Arteriovenous malformations
Epithelioid hemangioma	Arteriovenous fistula (congenital)
Pyogenic granuloma (lobular capillary hemangioma)	
Others	*Combined vascular malformations*
	Capillary–venous malformation (CVM)
Locally aggressive or borderline vascular tumors	Capillary–lymphatic malformation (CLM)
Kaposiform hemangioendothelioma	Capillary–arteriovenous malformation (CAVM)
Retiform hemangioendothelioma	Lymphatic–venous malformation (LVM)
Papillary intralymphatic angioendothelioma (PILA), Dabska tumor	Capillary–lymphatic–venous malformation (CLVM)
Composite hemangioendothelioma	Capillary–lymphatic–arteriovenous malformation (CLAVM)
Kaposi sarcoma	Capillary–venous–arteriovenous malformation (CVAVM)
Others	Capillary–lymphatic–venous–arteriovenous malformation (CLVAVM)
Malignant vascular tumors	
Angiosarcoma	
Epithelioid hemangioendothelioma	
Others

CORTICOSTEROIDS

Glucocorticoids at varying doses have been used for many decades as the first line of treatment for cutaneous hemangiomas and HHs. A possible mechanism is the negative effect of steroids on angiogenesis. Administration of 2–5 mg/kg of oral prednisolone or an intravenous equivalent is commenced for patients with hemodynamically significant shunts or signs of CHF. Response rates in the literature vary, with good responses ranging from 30% to 75% for multifocal and diffuse disease.[3,25] Steroids may also be indicated for coexisting cutaneous lesions that may threaten vision (e.g., eyelids) or be life-threatening (e.g., paratracheal or pharyngeal lesions). Lesions have been reported to stabilize between 2 and 4 months. The duration of therapy is guided by serial imaging and generally ranges from 5 to 8 months.[3,11,25]

CHEMOTHERAPEUTIC AGENTS

Interferon alpha has been used in corticosteroid unresponsive cases with promising results. In a report by Ezekowitz et al., liver hemangiomas regressed by 50% or more in 18 of 20 patients receiving interferon alpha-2a (up to 3 million units per square meter BSA) after an average of 7.8 months with no long-term adverse effects. However, its use has been guarded since 6.1% of children younger than 1 year experienced spastic diplegia and motor developmental disturbances after receiving interferon.[26,27]

Vincristine is a mitotic inhibitor that blocks the formation of tubulin microfibrils and arrests mitosis in the metaphase. It has been used in steroid-resistant, life-threatening hemangiomas at a dose of 1–2 mg/m^2. The high content of tubulin in the endothelial cells of hemangiomas makes this tumor particularly sensitive to vincristine.[28,29]

ENDOVASCULAR INTERVENTIONS

Use of angiography and embolization of arteriovenous shunts, though not curative, can provide major symptomatic relief from the hemodynamic effects of high-flow shunts in hemangiomas. Hemangiomas can derive collaterals from any of the hepatic, phrenic, intercostal, superior mesenteric, or adrenal arteries. It has been indicated primarily for CHF refractory to medical management, steroids, or additional chemotherapy. It has also been employed to shrink large hemangiomas symptomatic by the mass effect causing caval compression or abdominal compartment syndrome. An angiographic classification has been proposed based on the number of lesions; flow characteristics (high vs low); presence; type of shunt (arteriovenous, arterioportal, or portovenous); and major anomalies of hepatic

vessels (particularly venous varices).[30] The best response to embolization is found in patients with macroscopically visible shunts on angiography associated with single or multifocal lesions. Hemangiomas with extensive portal venous supply are more difficult to treat and may require multiple embolizations.[30] There is a risk of fatal hepatic necrosis after hepatic arterial embolization. The expertise required to perform and interpret angiography in this group of infants is generally found only in highly specialized referral centers.

SURGERY

Liver resections for hemangiomas have declined with better understanding of the biologic behavior of these tumors, improvements in pharmacotherapy, advances in endovascular techniques, and better pediatric intensive care. Reports have argued for surgery to be a last recourse after pharmacotherapy for the tumor, medical management of CHF, and endovascular interventions have all failed to achieve symptomatic control and tumor regression.[11,30,31] Kassarjian et al.[30] reported a series of 15 patients managed with endovascular interventions with one death in a patient who had diffuse liver hemangioma, severe CHF, and hypothyroidism. Dickie et al.[11] reported a series of 16 patients with no mortality and only 2 patients who required surgery (a left lobectomy and an orthotopic liver transplant). In contrast, Moon et al. have employed hepatic resection as a primary treatment modality for solitary, resectable, and symptomatic lesions. They used hepatic artery embolization as a second line of treatment, with one death from postoperative hemorrhage among nine patients who underwent surgery. Surgery and open biopsy are also indicated when a distinction cannot be made between a HB and a hemangioma.[25]

LIVER TRANSPLANTATION

A small number of patients with diffuse hepatic lesions replacing most of the hepatic parenchyma develop life-threatening complications including CHF, consumptive coagulopathy, abdominal compartment syndrome, and multiorgan failure. Because these patients may be those most likely to benefit from liver transplantation, early involvement of the transplant team has been advocated if there is a poor response to initial pharmacotherapy.[3] Embolization, even in the context of diffuse lesions, has been shown to prevent transplant.[31] The outcome following transplant is varied, though some authors report good outcomes.[32–34]

FUTURE DIRECTIONS

The classification and treatment of hepatic IHs will continue to evolve. Prospective characterization of patients will further the understanding of these uncommon tumors. While there is reasonable concordance about classification of GLUT1-positive multifocal or diffuse liver lesions, there remains discord in the biologic, clinical, and radiologic characterization of certain solitary liver vascular tumors. The Children's Hospital of Boston has proposed and created an Internet-based registry for longitudinal accrual of patients with liver hemangiomas.[3]

Antiangiogenic drugs show potential in the treatment of liver hemangiomas. Bevacizumab, a recombinant monoclonal antibody against VEGF, was incidentally found to reduce the size of liver lesions significantly in a patient with colorectal adenocarcinoma initially suspected to be metastasis, but later found on biopsy to be hemangiomas.[35] A similarly dramatic response was seen in a 41-year-old patient with pulmonary epithelioid hemangioendothelioma.[36]

Mesenchymal hamartoma of the liver

Mesenchymal hamartoma of the liver (MHL) is the second most common benign liver tumor in children after hemangiomas, and typically presents as a large benign multicystic liver mass.[37] MHL has been reported in the literature to compose 6%–8% of benign pediatric liver tumors.[38–41] Median age of diagnosis is 10 months, with 80% of cases diagnosed by 2 years of age and 95% by 5 years.[40,41] Rarely, this disease can be detected in adults,[42] and the tumor is reported to have a slight male predominance.[37,40,41,43] Historically, it was described under multiple names including pseudocystic mesenchymal tumor, giant cell lymphangioma, cystic hamartoma, bile cell fibroadenoma, hamartoma, and cavernous lymphangiomatoid tumor.[44] The understanding of the biology of this tumor has evolved greatly since it was definitively described in 1956 by Edmondson.[45] Mesenchymal hamartoma must be distinguished from other congenital and infective cystic diseases, hemangiomas, and other liver tumors.

PATHOLOGY AND PATHOGENESIS

The right hepatic lobe is affected more frequently than the left (3:1), and the mass can sometimes be pedunculated.[46] A small proportion of cases may involve both lobes.[1,37] Mesenchymal hamartomas usually contain both cystic and solid components, the proportion of which varies. About 50% are multicystic, with the intervening myxoid stroma containing fibroblasts, blood vessels and lymphatics, collagen, bile ductules, and islands of hepatocytes. Less commonly, the cysts can be very small and sometimes absent, resulting in a predominantly solid tumor.[40,47] The cystic spaces are filled with a clear or mucoid liquid and may or may not be lined by epithelium, the latter seen more often in larger cysts. Tumors can be very large, up to 30 cm in diameter and weighing up to 3 kg. Over 85% of tumors in the case series reported by Kim et al.[47] were larger than 10 cm at diagnosis. Mesenchymal hamartomas are usually well circumscribed and are surrounded by a rim of compressed hepatic parenchyma but are devoid of a true capsule.[37] There have been a few reports of multifocal MHL. Small satellite lesions at the margins of the tumor have been described and may explain recurrent disease after excision of the main tumor.[48]

The pathogenesis of this tumor is not clearly defined. The three leading theories are as follows: (1) abnormal embryologic development of the mesenchyme, producing

obstruction of the biliary tree as it develops, causing cystic, anaplastic, and proliferating bile ducts with most of the proliferative growth just before or after birth, since no mesenchymal mitotic activity is seen histologically[40]; (2) abnormal development of the vascular supply with ischemic necrosis and reactive cystic changes[49]; and (3) abnormal proliferation of the embryologic hepatic mesenchyme with elevated expression of fibroblast growth factor-2 (FGF-2).[50] There are associations with congenital heart disease, gut malrotation, omphalocele, myelomeningocele, Beckwith–Wiedemann syndrome, and breakpoint abnormalities on chromosome 19 (bands 19q13.3 or 19q13.4).[37,51–53]

Some have argued that MHL may be true neoplasms. The histopathologic and immunohistochemical similarities between undifferentiated embryonal sarcoma (UES) of the liver and mesenchymal hamartoma can be striking. It has been postulated that UES—with its onset in older children, benign bile ductular elements within a malignant mesenchyme, its predisposition to the right lobe, and occasional pedunculation—may be preceded by a mesenchymal hamartoma.[54,55] Several reports describe cases of UES arising within a previous MHL, two of which occurred after incomplete excision. Aneuploidy has been detected by flow cytometry in two of eight mesenchymal hamartomas in one study.[55] Cytogenetic abnormalities involving the same breakpoint on chromosome 19 (band 19q13.4) now have been reported in nine cases, three of which involved a UES originating within an MHL.[51,56–58] These karyotypic and cytogenetic abnormalities in at least some MHLs may indicate a clonal defect.

CLINICAL PRESENTATION

Mesenchymal hamartomas present most commonly as abdominal distention or an upper abdominal mass. Large tumors can cause respiratory distress or compression of the inferior vena cava with distended superficial abdominal veins or lower limb edema. Abdominal pain is unusual in children but more common in adults. Examination reveals a large, smooth, nontender mass in the upper abdomen. The tumor can be detected on prenatal ultrasound and may cause fetal hydrops, polyhydramnios, and fetal demise.[59,60] Case reports of MHL describe presentation with obstructive jaundice, vascular steal phenomenon, high-output cardiac failure, and perinatal tumor rupture in the newborn.

INVESTIGATIONS

Liver function tests are usually normal. Serum AFP concentrations may be variably elevated confounding the differential with HB. Levels return to normal after tumor removal, but may take up to a year due to liver regeneration. Thus, MHL should be distinguished from HB and may require biopsy.

A CT or ultrasound examination is diagnostic in most patients. The typical finding of a multiseptated cystic tumor with distinct margins is rarely seen in other pediatric tumors and is diagnostic of a mesenchymal hamartoma. The cystic areas appear hypodense and hypovascular on imaging. Solid areas (within mixed solid-cystic or predominantly solid tumors), septae, and peripheral areas may show heterogenous enhancement after intravenous contrast on CT.[47,61] The differential diagnosis in totally solid tumors in newborns and infants should include various hepatic tumors such as HB, hepatocellular carcinoma (HCC), and hemangiomas.

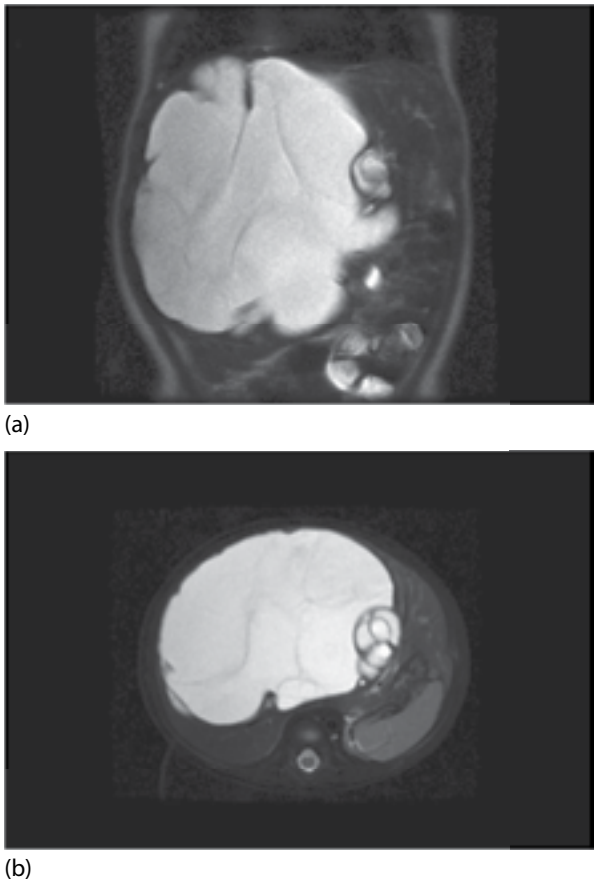

Figure 93.3 **(a)** Axial and **(b)** coronal views of the T2-weighted MRI of a large mesenchymal hamartoma showing a multiseptate cystic tumor. The patient underwent enucleation of the tumor.

On MRI, lesions typically have a low intensity on T1-weighted sequences, but have variable signal intensity on T2-weighted sequences. Where diagnosis is in doubt, the pathology is usually confirmed after resection of the tumor or by an open or percutaneous tumor biopsy (see Figure 93.3a and b).

TREATMENT

Management of MHL remains controversial. While spontaneous regression has been described, there is a lack of long-term follow-up and the safety of this approach cannot be determined. In the past, recommendations were made for nonradical resection, but there have been reports of late recurrence.[62–64] Flow cytometry studies have revealed that some MHLs are aneuploid, a finding typically observed in malignant tumors. As many controversies exist regarding the histogenetic origin of MHL and UES in addition to findings of chromosomal translocation, aneuploidy, and reports of coexistent MHL and UES, the disease is best treated by

complete tumor resection, either non-anatomically with a rim of normal tissue or as an anatomic hepatic lobectomy.[37,62,65,66] While the tumors themselves are not very vascular, the surrounding compressed hepatic parenchyma can be very vascular.

In the very rare case, a liver transplantation may be an option for the recurrent or unresectable MHL. The United Network for Organ Sharing (UNOS) group reported two cases of transplants performed in children who had progressive liver failure after resection of MHL, one of whom died from postoperative bleeding. A third case was reported of a newborn girl who developed a diffuse hemangioma of the liver remnant 4 months after a resection for MHL.[23,67,68]

Kaposiform hemangioendothelioma

KHE is a relatively uncommon vascular tumor often associated with KMP. The hallmark features of KMP include an enlarging vascular lesion, microangiopathic hemolytic anemia, thrombocytopenia, and a consumptive coagulopathy that results in a life-threatening hemorrhage.[24] KHE may occur in the extremities, cervicofacial, thoracic, or retroperitoneal locations. Retroperitoneal tumors have been found to extend to involve the liver, porta hepatis, pancreas, and mesentery. Mortality may be as high as 60% for those tumors that involve the retroperitoneum.[69] In regards to nomenclature, it is generally accepted that tufted angioma and KHE exist on a spectrum and are synonymous tumors.[24]

PATHOLOGY AND PATHOGENESIS

On histology, there are sheets or lobules of spindled endothelial cells and dilated lymphatic channels that show aggressive infiltration of normal tissue. Vascular lumens are filled with erythrocytes and hemosiderin suggestive of stasis. In contrast to the endothelial cells in IH, the endothelial cells in KHE do not express GLUT-1.

CLINICAL PRESENTATION

KHEs typically present as solitary lesions at birth or early infancy with equal gender ratio. Most cases of KHE have a classic presentation of a solitary ill-defined plaque that is tense, edematous, violaceous, and warm to palpation. The lesions are often large (>5 cm) and have episodic engorgement. The associated thrombocytopenia in KMP can be profound ($<50 \times 10^9$/mL) as the platelets are sequestered within the tumor resulting in a platelet half-life of 1 to 24 hours. As a result, patients can be at risk of intracranial, pleural, pulmonary, peritoneal, and GI hemorrhages.[24]

INVESTIGATIONS

The imaging modality of choice for the disease is MRI with and without gadolinium. In MRI, the tumor will have enhanced T2-weighted images. Other defining characteristics include an ill-defined and infiltrative tumor penetrating multiple contiguous layers. Osteolysis may be present when KHE abuts bone. The tumor has small feeding and draining vessels relative to tumor size, and the thickening and edema of the skin will appear as stranding in the subcutaneous fat.

TREATMENT

KHE may regress with time, but a complete involution is infrequent. Areas that do undergo involution often appear as fibrotic and firm capillary malformation. The treatment for KHE with KMP is primarily medical as the tumor is often too extensive or the risk of severe bleeding is too high to be amenable for surgical resection. Successful treatment of retroperitoneal KHE with alpha-interferon has been reported, but for tumor refractory to this treatment, success has been reported with vincristine, combined with cyclophosphamide, actinomycin D, and methotrexate.[70]

In general, platelet transfusions are not advised unless there is active bleeding or in a perioperative context as the administration of platelets may actually promote tumor growth through intralesional clotting and the release of proangiogenic proteins. Heparinization is not indicated because of bleeding risk and minimal platelet effects. Should the patient develop hypofibrinogenemia (<100 mg/dL), fresh frozen plasma or cryoprecipitate can be administered.

Focal nodular hyperplasia

The diagnosis of focal nodular hyperplasia (FNH) has been reported for all ages, from newborns to the elderly. It is an infrequent diagnosis in newborns and has been reported in association with other hepatic lesions of both benign and malignant categories. FNH is a benign epithelial tumor referred to in literature under many names including benign hepatoma, solitary hyperplastic nodule, focal cirrhosis, cholangiohepatoma, and mixed adenoma.[71] Similar to other benign tumors, smaller lesions may be asymptomatic, whereas larger lesions may exert mass effect and present with symptoms such as abdominal pain. The most widely accepted theory is that FNH results from vascular abnormalities that are either acquired or congenital.[72] FNH is a well-circumscribed lobulated lesion composed of bile ducts and a central stellate scar, which contains blood vessels that supply the hyperplastic tissue. The tumor does not have a true capsule but is often surrounded by fibrous tissue. On microscopic analysis, the proliferating cells are practically identical to the surrounding hepatocytes.

FNH is suggested by ultrasound findings of a well-demarcated, homogenous mass that is hyperechoic. The mass is more appropriately imaged with CT or MR angiography. The tumors typically have normal accumulation of ^{99m}Tc sulfur colloid on liver scintigraphy. Although the central stellate scar is a characteristic finding, the radiographic appearance of FNH can be variable. Gadoxetic acid (EOVIST) enhanced MRI has emerged as an additional modality for differentiating FNH from hepatic adenoma.[73] Spontaneous regression of FNH is rare, and complete surgical resection of biopsy-proven FNH is not mandatory in an asymptomatic patient. In symptomatic patients, where biopsy is nondiagnostic, or

patients in whom the diagnosis of malignancy has not been definitively ruled out, surgical excision is required.

Hepatic adenoma

Hepatic adenoma is very rare in the newborn period and can be difficult to distinguish from other more common tumors in this age range, even with multimodal imaging. One series of 17,417 perinatal autopsies found only one hepatic adenoma.[74] In a single-center series of 178 primary hepatic tumors treated over a 57-year period, two cases of hepatic adenoma were noted.[75] One case report demonstrates the detection of a hepatic adenoma in utero during routine prenatal ultrasonography.[76] The majority of neonatal hepatic adenomas occur in a sporadic manner without a known predisposing factor. Imaging typically demonstrates hepatic adenomas as a solid mass. Multimodal imaging including ultrasonography, CT, ^{99m}Tc sulfur colloid liver scintigraphy, and MRI is found to be more helpful than a single modality alone. The appearance of a hepatic adenoma can be highly variable and nonspecific. The mass is usually hypoechoic on ultrasound but may be hyperechoic; the mass is not typically cystic. On noncontrast CT, the adenoma is likely hypodense. In contrast-aided studies, the arterial phase is usually homogeneous in enhancement and the portal phase is hypodense.[76] The MRI appearance can be variable and difficult to distinguish from HCC, HB, and focal nodular hyperplasia. The common pattern observed is mild signal hypointensity in the T1-weighted images and hyperintensity in the T2-weighted images.

TREATMENT

The potential risk of life-threatening hemorrhage from a hepatic adenoma is 20%. Subsequently, complete surgical resection is recommended when technically feasible. Transarterial embolization (TAE) is preferred in instances of tumor rupture and intraperitoneal hemorrhage with hemodynamic stability.[77] TAE has also been used to electively reduce tumor mass in unruptured hepatic adenomas with up to 80% of cases showing stability, regression, or complete involution.[78,79] Additional management includes close follow-up with serial liver imaging and AFP monitoring, as it may be difficult to rule out HB. The risk of malignant transformation for a hepatic adenoma remains controversial.[75] It is recommended that hepatic adenoma be considered in the differential diagnosis even when a cystic liver mass is suggested on a fetal ultrasound. Contemporary management has included percutaneous radiofrequency ablation as an additional modality for treatment.[80]

MALIGNANT LIVER TUMORS

Hepatoblastoma

EPIDEMIOLOGY

The age-adjusted incidence for primary liver cancer for the period 2008–2012, as published by the Surveillance Epidemiology and End Result (SEER) program of the National Cancer Institute, is 11.1 per million in the <1 year age group, 6.7 per million in the 1- to 4-year-old group, and 0.7 per million among children 5–9 years old. HB comprises the overwhelming majority of malignant primary liver tumors in these age groups (Table 93.3).[81] Incidence of HB appears relatively consistent between nations with most estimates of rates among children, showing no discernible differences between continents.[82] Five percent of all cancers and more than 95% of hepatic cancers in this age group are HBs. In the Pediatric Oncology Group series, 11% of HBs occurred in the first 6 months of life. Of these, 50% were congenital, as evinced by their size at the time of diagnosis, usually at the age of 2–3 months.[83] HBs accounted for 1% of all liver and bile duct tumors diagnosed in the United States between 2008 and 2012. The incidence of HB appears to be increasing at a rate of 1.2–1.5 per million per year, likely due to the increase in survival of premature low and very low birth weight infants, a factor that has been associated with HBs.[84–87]

Table 93.3 Age-adjusted and age-specific SEER cancer incidence rates (per million), 2008–2012

Group	Age <1 year	Age 1–4 years	Age 5–9 years
Hepatic tumors	11.1	6.7	0.7
Hepatoblastoma	11.0	6.5	–

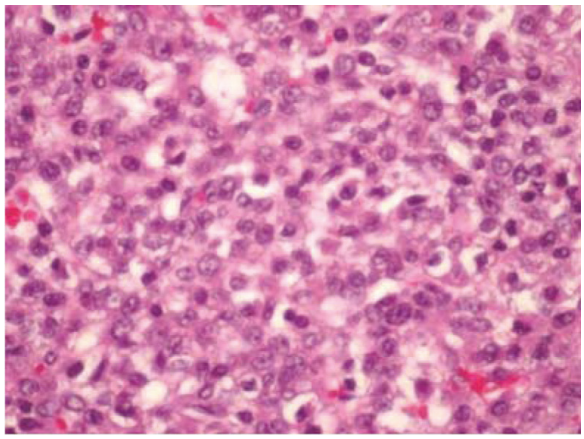
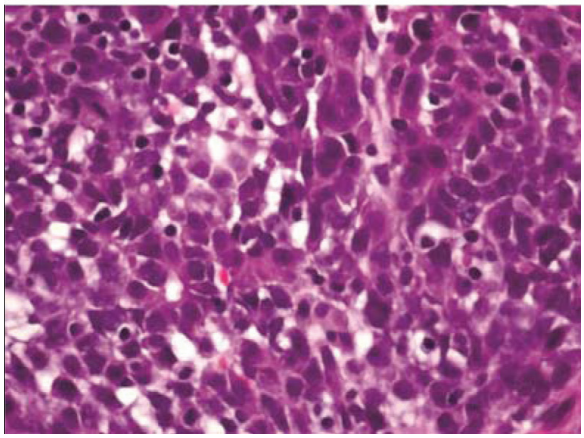
HISTOLOGY

HB is an embryonal tumor thought to arise from a hepatocyte precursor and usually demonstrates combinations of epithelial, mesenchymal, undifferentiated, and other histological components. HBs are broadly classified as epithelial or mixed. Epithelial HBs consist of fetal (Figure 93.4a), embryonal, macrotrabecular, small-cell undifferentiated (Figure 93.4b), and cholangioblastic types. The mixed HBs consist of stromal derivatives and teratoid types (Table 93.4).[88] Given the histologic heterogeneity of HB, biopsy samples may not always represent the entire tumor. Among all cases, 85%–90% contain both fetal and embryonal cells, and 20% may have stromal components.[83,89]

Pure fetal histology is thought to be the most favorable type, with various studies demonstrating its better prognosis with survival rates reported near 100%.[90,91] The small-cell undifferentiated type is particularly aggressive, especially when present in a significant portion of the HB (75% or so) as the sole cell type. This histology is more common in neonates and infants. AFP elevations may not be observed as seen with other histologies.[92] It has a poor prognosis due to lack of response to current therapy. The



(a)



(b)

Figure 93.4 Histological subtypes of HBs. **(a)** Fetal type and **(b)** small-cell undifferentiated.

significance of smaller proportions of small cells is not yet known.

GENETIC CHANGES

Most HBs are sporadic; however, various genetic anomalies and syndromes are known to be associated with HB including low and very low birth weight, trisomy events, familial adenomatous polyposis (FAP), Gardner's syndrome, Beckwith–Weidemann syndrome, and hemihyperplasia.[93–96] The risk of HB rises 1000- to 2000-fold in children with this family history, and approximately 800-fold in those with a history of FAP.[97–101]

HB is tightly linked to excessive Wnt/β-catenin signaling. There is a high rate (50%–90%) of mutations found in *CTNNB1*, which encodes β-catenin, placing HB among the most common human tumors with constitutive activation of β-catenin/Tcf signaling.[102–104] *APC* gene (involved in degradation of β-catenin) mutations have been characterized regularly in kindred of FAP (risk of HB ~1%) but are not as commonly seen in sporadic HB. Loss-of-function somatic mutations of tumor suppressor genes *AXIN1* and *AXIN2* whose products affect the β-catenin degradation have also been reported in some HBs.[105]

Cairo et al.[106] reported two major molecular subclasses of HBs that evoke early and late phases of prenatal liver development. Using a 16-gene signature that correlated with the phase of liver development, they established a tight correlation between the stage of hepatic differentiation and clinical behavior—notably, vascular invasion, metastatic spread, and patient survival. This demonstrated strong prognostic relevance compared to clinical criteria (tumor stage and predominant histology) in multivariate analysis. Also, *Myc* overexpression has been shown to induce HB-like tumors in mice and plays a critical role in aggressive phenotype of liver tumors originating from hepatic progenitor cells.[105,106]

Other molecular mechanisms implicated in the growth of HBs include the overexpression of insulin-like growth factor-I[107,108] and downregulation of the tumor suppressor gene, *RASSF1A*, by promoter methylation.[109,110] Methylation of *RASSF1A* gene was an independent risk factor in multivariate analysis. Upregulation of the *MAPK* pathway has also been noted in aggressive HBs with a small-cell undifferentiated component.[111]

Cytogenetic analyses of HBs have shown recurring patterns of chromosomal abnormalities. The most common involve trisomies, particularly of chromosomes 2, 8, and 20, among others.[94] Numerical aberrations as well as unbalanced translocations involving the proximal region of chromosome 1q are characteristic of HB.[112] More specifically, bands 1q12-21 have been described as a location of recurring translocations in HB and were found in 20 of 55 patients in a series of HBs.[113] The *NOTCH2* gene, which encodes a transmembrane receptor critical to the development of the liver, also on chromosome 1, has been shown to have aberrant overexpression in 92% of HB cases, suggesting its role in HB pathogenesis by wrongly maintaining hepatoblast populations.[112,114]

CLINICAL FINDINGS

The majority of infants with HB present with an asymptomatic abdominal mass noticed incidentally by a relative or a pediatrician. An array of nonspecific symptoms, such as abdominal pain, pyrexia, irritability, weight loss, or gastrointestinal disturbances, may occur in a small percentage of patients, especially those with advanced disease. Clinical examination usually shows an expansile solitary mass in the liver. Thrombocytosis, with the platelet count ranging in the millions, is a well-known, albeit uncommon, feature of HB. Thrombopoietin production by the tumor has been proposed as possible cause of the thrombocytosis.[115,116] Hormone elevations that lead rarely to symptoms are due to human beta chorionic gonadotropin (β-hCG), testosterone, adrenocorticotrophic hormone, or parathormone-related peptide.[117,118]

AFP is markedly elevated in more than 90% of patients with HB, in whom it is used as a diagnostic tool and as a tumor marker to monitor therapeutic response; however, AFP elevations are not pathognomonic of disease. The half-life of AFP in the first month of life is between 5 and 6 days, increasing to approximately 42 days by 6 months of age.

Table 93.4 Classification of hepatoblastomas

Epithelial	
Fetal	"Well differentiated": uniform (10–20 μm in diameter), round nuclei, cords with minimal mitotic activity (<2 per ×10/400 microscopic fields), EMH[a] "Crowded" or mitotically active (>2 per ×10/400 microscopic fields); conspicuous nuclei, less glycogen "Pleomorphic, or poorly differentiated": moderate anisonucleosis, high N/C, nucleoli "Anaplastic": marked nuclear enlargement and pleomorphism, hyperchromasia, abnormal mitoses
Embryonal	10–15 μm in diameter, high N/C, angulated nuclei, primitive tubules, EMH
Macrotrabecular	Epithelial HB (fetal or embryonal) growing in trabeculae of >5 cells thick (between sinusoids)
Small-cell undifferentiated	5–10 μm in diameter, no architectural pattern, minimal pale amphophilic cytoplasm, round to oval nuclei with fine chromatin and inconspicuous nucleoli, +/− mitoses; +/− INI1[b]
Cholangioblastic	Bile ducts, usually at periphery of epithelial islands, can predominate
Mixed	
Stromal derivatives	Spindle cells ("blastema"), osteoid, skeletal muscle, cartilage
Teratoid	Mixed, plus primitive endoderm; neural derivative, melanin, squamous, and glandular elements

[a] EMH = extramedullary hematopoiesis.

[b] Pure small-cell undifferentiated needs to be differentiated from MRTs (discohesive, eccentric irregular nuclei, prominent nucleoli, abundant cytoplasmic filaments including cytokeratin and vimentin, negative nuclear INI).

Levels in preterm babies (earlier than 37 weeks of gestation) are significantly higher with a negative correlation between gestational age and AFP levels.[119] AFP levels are usually less than 10 ng/mL by 1 year of age, though persistent elevations, especially in preterm babies without any known associated factors, have been observed (see Table 93.5).

Table 93.5 Average normal serum alpha-fetoprotein level in infants

Age	No. of patients analyzed	Mean ± SD (ng/mL)
Premature	11	134,734 ± 41,444
Newborn	55	48,406 ± 34,718
Newborn to 2 weeks	16	33,113 ± 32,503
2 weeks to 1 month	43	9452 ± 12,610
1 month	12	2654 ± 3080
2 months	40	323 ± 278
3 months	5	88 ± 87
4 months	31	74 ± 56
5 months	6	46.5 ± 19
6 months	9	12.5 ± 9.8
7 months	5	9.7 ± 7.1
8 months	3	8.5 ± 5.5

IMAGING

Quality imaging of patients with HB is crucial for proper staging and risk stratification so patients may receive optimal treatment. Three-phase abdominal CT (noncontrast, arterial, and venous phases) or MRI and magnetic resonance angiogram (MRA) with contrast can be performed at presentation, according to the local practice. MRI with EOVIST contrast (preferentially taken up and excreted by hepatocytes) is being used with increasing frequency.[120] A Doppler ultrasound (if an MRA has not been performed) will define any involvement of the portal or hepatic veins and inferior vena cava. It can be difficult to distinguish direct involvement of the veins from external compression.

CT of the chest (without contrast) and a anteroposterior (AP)/lateral chest x-ray should be performed on all patients with a primary liver tumor. Technetium-99m methylene-diphosphonate nuclear bone scintigraphy is not routinely recommended due to the rarity of bone metastasis in HBs and is performed only if there is clinical suspicion.[121] The role of positron emission tomography (PET) is not routine in HBs. A small series showed fluoro-deoxyglucose uptake in the primary tumor, and additionally a small series evaluated PET/CT use for restaging of patients; however, larger studies need to confirm such findings and outline a role for this modality.[122,123] As resection of the primary tumor is essential for survival, liver imaging must define the segmental involvement of the liver and associated vasculature, both of which are indicators of resectability (see Figure 93.5a and b).

STAGING

Two systems for staging pediatric liver tumors are used: one for treatment-naive patients and one based on postoperative extent of disease. Pretreatment staging is essential for risk stratification and outcome assessment when neoadjuvant treatments are used. However, post-operative staging systems incorporate histologic information that otherwise may not be available at time of diagnosis.[95]

The North American Children's Oncology Group (COG) employs a postoperative staging scheme (see Table 93.6). Risk stratification in the current COG HB protocol is based on the predominant tumor histology, presence of gross residual disease, distant metastasis, and the presence or absence of a low AFP (<100 ng/mL) at diagnosis (see Figure 93.6).

The Société Internationale d'Oncologie Pédiatrique/International Society of Pediatric Oncology Epithelial Liver Tumor Study Group (SIOPEL) introduced the PRETEXT (pretreatment extent of disease) system of staging liver tumors,[124,125] which defines the liver in four sections based on Couinaud's system of segmentation of the liver: (1) left lateral (Couinaud 2 and 3); (2) left medial (Couinaud 4);

Table 93.6 Children's oncology group staging system for pediatric liver tumors

Stage I	Complete gross resection at diagnosis with clear margins
Stage II	Complete gross resection at diagnosis with microscopic residual disease at the margins of resection
Stage III	Biopsy only at diagnosis; or gross total resection with nodal involvement; or preoperative tumor spill/rupture; or incomplete resection with gross residual tumor
Stage IV	Distant metastatic disease at diagnosis

(3) right anterior (Couinaud 5 and 8); and (4) right posterior (Couinaud 6 and 7; see Figure 93.7). Risk stratification in PRETEXT is based on the number of contiguous tumor-free regions of the liver, and letters are assigned for the involvement of the caudate lobe (C); invasion of the vena cava or all three major hepatic veins (V); portal vein (P); contiguous extrahepatic growth (E); tumor rupture or hemorrhage (H); and distant metastasis (M; Table 93.7). PRETEXT stage has been shown to be an independent predictor of 5-year overall survival.[125]

The COG has used the PRETEXT staging system as an objective tool to monitor the effect of neoadjuvant chemotherapy and to determine the timing and extent of surgical resection.[126] It is hoped that this tool will allow better intergroup collaboration in the development of new therapeutic strategies for the highest-risk groups that continue to have a poor response to current treatment approaches. Recent analysis of a combined database of 1605 HB cases by the Children's Hepatic Tumors International Collaboration (CHIC) confirmed prior prognostic factors and yielded new ones for HB. Previous cooperative group studies identified variables such as PRETEXT stage, presence of metastatic disease, and very low serum AFP (<100 ng/mL) as poor prognostic factors. The CHIC group identified other variables such as spontaneous tumor rupture at enrollment, tumor multifocality, macroscopic vascular tumor invasion, contiguous extrahepatic tumor extension, older age at diagnosis, and very high (>1 million ng/mL) or borderline low AFP levels (100–999 ng/mL) as additional factors portending a poor prognosis.[87]

RISK GROUPS

The PRETEXT system established a common language for description of pediatric liver tumors and is used as the foundation for risk stratification for HB patients.[95,124] Risk group stratification allows clinicians to identify optimal treatment modalities based on their PRETEXT staging combined with histology and AFP levels. Each major study group has subtle variations on the definitions of groups between very

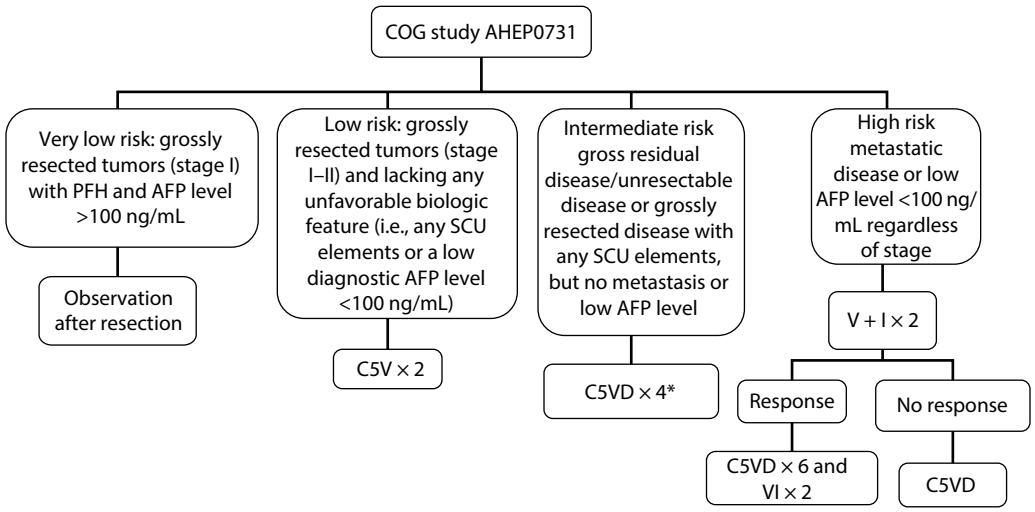

Figure 93.6 Diagram presents the patient groups and treatment algorithms for the Children's Oncology Group (COG) HB study AHEP0731 (NCT#00980460). Patient risk stratification is based on COG criteria. (Adapted from The Children's Oncology Group. Risk-based therapy in treating younger patients with newly diagnosed liver cancer [NCT00980460]. low risk, low/standard risk, intermediate risk, or high risk groups, which can be seen in Table 93.8.[120]

TREATMENT

The treatment of HBs is a success story in pediatric oncology. Overall survival has increased from 30% to 70% over the past few decades.[127] The addition of platinum-based chemotherapy to treatment regimens, along with advancements in surgical techniques, improved prognosis dramatically, with 5-year relative survival rates between years 2005 and 2011 reported as 86.4% for age < 1 year and 80.7% for ages 1–4 years.[81,92] Various collaborative groups have researched and developed successful treatment strategies for HBs (COG, SIOPEL, German Society for Pediatric Oncology and Hematology [GPOH], and the Japanese Study Group for Pediatric Liver Tumors [JPLT], among others).

Table 93.8 PRETEXT in risk stratification schemes of the major study groups

	COG	SIOPEL	GPOH	JPLT
Very low risk	PRETEXT I or II, pure fetal histology, and primary resection			
Low risk/ standard risk	PRETEXT I or II, any histology, primary resection	PRETEXT I, II, and III	PRETEXT I, II, and III	PRETEXT I, II, and III
Intermediate risk	PRETEXT II, III, IV unresectable at diagnosis V+, P+, E+SCU			PRETEXT IV, any PRETEXT with rupture, N1, P2, P2a, V3, and V3a multifocal
High risk	Any PRETEXT M+AFP level <100 ng/mL	Any PRETEXT V+, P+, E+, M+SCU AFP level <100 ng/mL tumor rupture	Any PRETEXT V+, P+, E+, M+multifocal	Any PRETEXT, M1, N2 AFP level <100 ng/mL

Active agents against HB are cisplatin, 5-fluorouracil (5-FU), vincristine, doxorubicin, ifosfamide, and irinotecan. The standard chemotherapy regimen in SIOPEL 1 was preoperative cisplatin (PLA) and doxorubicin (DO) (PLADO) and delayed surgery.[128,129] Cisplatin monotherapy for standard risk HB (SR-HB) was evaluated against PLADO in the SIOPEL-3 trial, where it was concluded that doxorubicin could be safely omitted in these patients.[130] A review of 151 patients with high-risk HB (HR-HB) treated with alternating cycles of cisplatin and carboplatin plus doxorubicin and delayed tumor resection showed improved survival rates for this risk group.[129] The COG uses C5FV (cisplatin + 5-FU + vincristine) as the standard chemotherapy regimen for low- and intermediate-risk tumors. The addition of doxorubicin to cisplatin-based therapy offered no survival advantage for low-risk (COG stage 1 or 2) tumors and was associated with increased incidence of adverse events. However, an improved event-free survival was noted in patients receiving cisplatin–doxorubicin compared with C5FV for stage III and IV patients.[127,131] The current COG study (AHEP-0731) randomizes intermediate risk HB to cisplatin, 5-FU, vincristine, and doxorubicin against standard therapy. The use of irinotecan as window therapy for high-risk HB is also being evaluated for stage IV HB, for which outcome on current therapy continues to be dismal (see Figure 93.6).

The key difference in approach between the COG and SIOPEL is the timing of surgery and the use of neoadjuvant chemotherapy. The COG's approach has been to primarily resect tumors where possible and subsequently administer adjuvant chemotherapy for tumors with histologies other than PFH. Neoadjuvant chemotherapy after open or percutaneous needle biopsy is given to infants who present with an unresectable tumor. The SIOPEL approach has been to treat all patients diagnosed with HB (based on imaging and image-guided percutaneous needle biopsy) with neoadjuvant chemotherapy. They have argued toward less extensive surgical resections and shown operations to be easier and safer in pretreated tumors. Biopsy of the tumor, which is a prerequisite for such an approach, has also been found technically safe with a very low risk of tumor spread.[132]

The timing of surgery after induction therapy is another consideration. The current COG and SIOPEL protocols recommend an assessment for resection after two cycles of chemotherapy followed by two further cycles if the tumor is unresectable. A study found no statistically significant decline in tumor volume after the second cycle of chemotherapy.[133] These findings were similar to those of a prior study from our institution on pediatric solid tumors that included three HBs.[134] This may have implications for reduced toxicities with shorter regimens and early referral for transplant in the absence of a response.

For multifocal, PRETEXT IV tumors, liver transplant has proved to be a viable option. Six-year tumor-free survival of 82% was achieved with primary liver transplant, compared to 30% for rescue transplants due to either tumor recurrence or technical failures. Live related donor and cadaveric liver transplantation had disease-free survival of 82% and 71%, respectively. Macroscopic venous invasion, though a significant factor in overall survival, is not a contraindication to transplant, so long as the transplant can be performed without leaving gross tumor behind.[135]

The significance of pulmonary metastasis at presentation and later is currently being evaluated. The incidence of pulmonary metastatic disease can be as high as 40%. The outcome of this group of patients is markedly poorer.[136,137] The Children's Cancer Group reported long-term survival with resection of pulmonary metastasis and systemic

chemotherapy where the lungs were the only site of metastatic disease and where the primary tumor had been successfully treated.[138,139] Meyers et al.'s[137] review of patients from the COG INT-0098 reported excellent outcome following pulmonary metastasectomy of lung metastasis detected at presentation (8 of 9 patients were long-term survivors), but a poorer outcome for pulmonary recurrence after chemotherapy, where 4 of 13 were long-term survivors.[137]

ADJUNCT THERAPIES

Transcatheter arterial chemoembolization (TACE), which uses a percutaneously placed intraarterial catheter, has emerged as an option in advanced, unresectable HBs (see Table 93.9). It has potential for making inoperable HBs resectable or transplantable.[140] Malogolowkin et al.[141] described the efficacy of TACE in a study including six patients with HB and found it to be well tolerated and allowed surgical resection of the primary tumor in tumors previously deemed unresectable.[141] Four series of HBs, which included 36 patients ranging from 50 days to 5 years of age, have reported a resectability rate of 88.8%.[142–145]

Further chemotherapeutic strategies for the treatment of HR-HB, especially small-cell undifferentiated HBs, which respond poorly to current chemotherapy protocols have been and continue to be investigated. A Phase II study from the COG evaluated the use of irinotecan (a topoisomerase 1 inhibitor) in children with refractory solid tumors and showed complete response in one of eight HB patients.[146] Irinotecan is currently being evaluated in HR-HB in the COG study AHEP0731, as well as a clinical trial from the National Cancer Institute (ClinicalTrials.gov Identifier: NCT00980460), and successful treatment has been reported in case studies and small series.[147–149]

Gene-directed therapeutic strategies being investigated include Bcl-2 silencing and the targeting of *Myc* and β-catenin genes. The use of gene therapy to activate 5-fluorocytosine (an inactive prodrug) to 5-fluorouracil has been described in *in vitro* studies.[150] The neurokinin-1 receptor (NK1R), bound by the peptide substance P (SP), has been shown to induce tumor cell proliferation, angiogenesis, and migration in various cancers, and is expressed in HB cells in pre- and post-chemotherapy samples.[151] Novel studies using HB cell lines (Huh6, HepT1, HepG2) to block NK1R function with a small molecule, aprepitant, have shown growth inhibition and apoptosis by inhibition of the canonical *wnt* signaling pathway, which potentially provides another therapy to augment treatment strategies for chemoresistant cancer cells.[152] A recent study by Waters et al.[153] demonstrated that a novel rexinoid, UAB30, was able to decrease cell survival *in vitro* and decreased tumor growth in xenograft models, suggesting a possible role in the treatment of HB after further investigation.

Malignant rhabdoid tumor

Malignant rhabdoid tumors (MRTs), were initially described as the rhabdomyosarcomatoid variant of Wilms tumor,[154] although they are now known to be a distinct pathology. These tumors more commonly present as CNS or renal tumors; however, they have also been described in the liver, lungs, and soft tissues. MRTs of the liver are poorly understood extremely rare tumors with a grave prognosis. They

Table 93.9 Reports of transcatheter arterial chemoembolization in unresectable hepatoblastoma

Reference	No. of patients	Age range	No. of treatments	Resectability	Overall survival	Complications of TACE
Han et al.[142]	4	8–22 months	2	4/4 underwent hepatic resections	100%, 16–52 months follow-up	None
Li et al.[143]	16	50 days to 60 months	1–3 (cisplatin/ Adriamycin)	13/16—complete resections (incl. one OLT) 3/16—partial resection	1-year OS: 87.5% 3-year OS: 68.7% 5-year OS: 50%	None
Xuewu et al.[144]	8	2–12 months	1–3 (Adriamycin/ vincristine/ cisplatin)	6/8—complete resection; 1/8—no surgery as tumor completely regressed; 1/8—died of pneumonia before surgery	15–49 months follow-up	One case of pneumonia
Oue et al.[145]	8	4–26 months	1 (heterogenous group, 3 patients received pre- or post-TACE chemotherapy)	8/8 resected (one patient had pulmonary metastasis)	6 of 8 disease free at 46 months; 2 of 8 died of metastatic disease	Fever

have sometimes presented with an abdominal mass, distention, or fever, elevated LDH, and normal or near normal AFP levels.[155] MRTs in all sites tend to present at a young age, with one series showing 4 of 19 patients at age 3 months old or younger.[156] Differentiating the tumor from a small-cell undifferentiated type HB can be difficult, as they share clinical and histological features.[157] The tumor is very friable, can present with rupture, distant metastases, and can bleed uncontrollably following biopsy. Deletions and mutations of the tumor suppressor gene, *SMARCB1* (also known as *hSNF5, INI1,* and *BAF47*), in chromosome band 22q11.2 have been demonstrated in MRTs, and the loss of *SMARCB1* immunostaining may be a reliable marker of rhabdoid tumors in children.[158,159] Germline *SMARCB1* mutations have been identified in up to 35% of patients. These patients have been shown to present at younger ages (~6 mo) and may carry a worse prognosis.[159]

MRTs are extremely difficult to treat with poor responses to cytotoxic chemotherapy, and reports of median survival near 15 weeks.[155,156] There are cases of long-term survival in a 13-month-old girl following right hepatectomy and multiagent chemotherapy with ifosfamide, vincristine, and actinomycin D[160]; and in a 3-year-old after combination chemotherapy with ifosfamide, carboplatin, and etoposide alternated with vincristine, doxorubicin, and cyclophosphamide as well as liver transplantation.[161]

Fibrolamellar HCC

Fibrolamellar HCC (FLHCC) is a rare primary liver tumor that typically presents in children and young adult patients with no background history of liver disease or hepatitis, and sporadic cases have been reported in infants.[162] The tumor was first described in 1956[45] as a variant of conventional HCC, but is now recognized as a unique pathologic entity. Patients typically do not have viral hepatitis or cirrhosis, and do not exhibit elevations in serum AFP. Recent advances in the tumor biology of FLHCC show a 400-kb deletion in one copy of chromosome 19 in tumor samples producing a chimeric transcript between the first exon of the heat shock protein, *DNAJB1*, with all but the first exon of the catalytic subunit of protein kinase A, *PRKACA*.[163] This chimera is a functional kinase, and few other changes are seen in the genomic DNA.[164] Total surgical resection is paramount in treatment of FLHCC, and outcomes have been reported to be more favorable for FLHCC than conventional HCC. Lymph node metastases are common, and presence of extrahepatic disease is a consistent, independent predictor of overall and recurrence-free survival.[165] Recent transcriptomic evaluation of FLHCC shows key oncologically relevant pathways to have elevated transcription levels, including EGF/ErbB and Wnt signaling pathways, which may lead to new avenues of treatment. Ongoing clinical trials are evaluating the use of an oral aurora kinase A inhibitor, the transcript of which was found to be elevated in FLHCC tumor samples (ClinicalTrials.gov identifier: NCT02234986).[166]

Germ cell tumors

While germ cell tumors in children are fairly common, their occurrence in the neonatal liver is quite rare. Large series of fetal and neonatal tumors spanning decades have documented only isolated cases in the liver. As a group, they account for around 2% of tumors in this age group.[1,167,168]

CHORIOCARCINOMA

Choriocarcinoma is a rapidly growing, hemorrhagic tumor of the trophoblastic tissues. The placenta is believed to be the site of origin, with subsequent hematogenous metastasis in the infant and/or mother. The liver is the most frequently involved site in infants. Choriocarcinoma in the neonatal period is a rare (approximately 1:40,000 pregnancies), life-threatening malignancy but one that is highly responsive to the appropriate early treatment when instituted.[169] The disease is generally recognized late in the neonate with median age of symptomatology at 1 month. Cases have been documented and treated successfully, both in the presence and absence of maternal or placental disease.[170–172] Bolze et al.[173] confirmed a case of transplacental transmission through tumor genotyping, strengthening the theorized mechanism of hematogenous spread from mother to child. The absence of placental disease can be explained by the presence of even a microscopic focus of primary disease in the placenta missed on histopathology; a placental focus of choriocarcinoma is not always present in maternal disease either.

Choriocarcinoma is detected easily in the newborn by the presence of an elevated serum β-hCG. The neonate usually presents with an abdominal mass, hepatomegaly, and anemia. This "infantile choriocarcinoma syndrome" was first described by Witzleben and Bruninga[174] in 1968 in infants aged 5 weeks to 7 months, though this can easily be applied to the newborn. The presence of choriocarcinoma in the mother who has delivered a live baby is rare and should prompt a screen for a neonatal tumor in the first month of life. Also, suspicion of choriocarcinoma in the neonate should prompt a search for the same in the mother. The tumor can metastasize rapidly to the lungs, brain, and skin, and usually is fatal within weeks owing to uncontrolled hemorrhage.[175]

If detected early, the tumor is highly chemosensitive to methotrexate and agents used for other germ cell tumors, such as etoposide, bleomycin, and cisplatin. Paclitaxel can be used as second-line chemotherapy for cisplatin unresponsive disease. Residual disease in the liver, lungs, or brain can be resected or observed as per the response monitored radiologically (CT/MRI) and biochemically (serum β-hCG). There have been an increasing number of reports of successful treatment for this disease.[171,176–181]

TERATOMAS

The few reported cases of teratomas of the liver in the newborn have been mature teratomas, though more examples of all kinds have been reported in infancy.[182–184] Interestingly,

a large series of teratomas in children included two liver tumors, both of which occurred in newborns.[185] The AFP level is usually elevated regardless of the presence or absence of malignancy. Treatment usually consists of resection and chemotherapy guided by the malignant cell type. Growing teratoma syndrome is defined as an enlarging mass that consists predominately of mature teratomas with normal or falling tumor markers. While this is of concern, most series describe an older patient population.[186,187]

PRIMARY YOLK SAC TUMORS

Primary yolk sac tumors are extremely rare and highly malignant. A total of eight cases are described in the literature. The tumor is thought to develop from germ cell precursors that become arrested during embryological migration, or to arise from pluripotent embryonic cells that escaped the influences of the differentiation process during embryogenesis.[188] Yolk sac tumors can occur in a pure form or, more commonly, in combination with other germ cell tumors. Hart reported the first yolk sac tumor of the liver in an 18-month-old boy in 1975. Lesions can present as a solitary mass or as multiple masses. Serum AFP is markedly elevated, and on diagnostic imaging, there is often a finding of central necrosis or intratumoral hemorrhage. It is important to differentiate primary yolk sac tumor from HB in view of potential therapeutic implications.

PRINCIPLES OF LIVER RESECTIONS

The details of individual major hepatic resections are beyond the scope of this chapter, and the reader is referred to a text on hepatobiliary surgery.[189] However, the general principles of liver resections in neonates and infants are similar to those in adults. The potential hazards are mainly blood loss and bile leak. Eighty-five percent of the liver can be safely removed in small infants. Liver regeneration is rapid and almost complete within 3 months.[190] Central hepatectomy has also been shown to be a feasible, though technically challenging, operation in children with HBs.[191] Values on liver function tests usually return to normal within a few weeks.

Bloodless hepatic dissection is crucial in newborns for which the blood volume is no more than a few hundred milliliters. The surgical approach is based on a thorough understanding of the hepatic anatomy as described by Couinaud.[192] Skilled anesthetic management and maintenance of a low central venous pressure (CVP) in the patient minimizes blood loss. Hepatic resections in children can be carried out through a transverse or subcostal incision, and vertical extension is often unnecessary. After division of the ligamentum teres and the falciform ligament, a thorough examination of the liver is undertaken to identify the site or sites of tumor involvement. Further mobilization of the left or right lobe is undertaken with division of the respective peritoneal reflections on the diaphragm. The mobilization of the right lobe is completed once the fibrous tissue over the inferior vena cava is divided with scissors or the endoscopic gastrointestinal anastomosis vascular stapling device (Endo-GIA, United States Surgical Corporation, Norwalk, CT). The use of intraoperative ultrasound at this stage is useful in identifying the location of hepatic vessels, particularly the hepatic veins.

Next, attention is turned toward establishing inflow control and identifying and preserving the components of the biliary tree. Control of the branches of the hepatic artery and the portal vein supplying the part of the liver to be resected can be achieved individually by extrahepatic dissection or by transecting the relevant pedicle within the substance of the liver. During left hepatectomy, the left branch of the portal vein and left hepatic artery are divided within the umbilical fissure. Dissection of the extrahepatic biliary structures is not necessary and carries the risk of inadvertent bile duct injuries, especially in the presence of variant anatomy. Division of the biliary radicals can be achieved at the time of parenchymal transection by dividing them laterally within the pedicles.

Establishing control of the venous outflow is the aspect of the operation most fraught with the risk of blood loss and air embolism. This dissection is performed with the patient in 15-degree Trendelenburg position and with the anesthesiologist maintaining a CVP of less than 5 mmHg. The individual hepatic veins are carefully dissected, divided within vascular clamps, and oversewn with 3-0 polypropylene sutures. Alternatively, they can be divided using the Endo-GIA vascular stapling device.

Division of the liver parenchyma should be considered to be more akin to fine dissection than a fracture and division. This may be accomplished by a simple crushing technique. We apply intermittent inflow occlusion (Pringle maneuver) for periods up to 7 minutes with 1-minute windows when hemostasis is achieved on the cut surface. The Glisson's capsule is scored with cautery and a Kelly clamp used to fracture the liver substance. A combination of titanium hemoclips and the Endo-GIA vascular stapler is used to transect the liver substance. We employ a saline-linked radiofrequency ablation device called TissueLink (TissueLink Medical Inc, Diver, NH, USA) and the argon beam coagulator to achieve hemostasis. We do not routinely employ drainage of the abdominal cavity.[193]

CONCLUSION

The understanding of hepatic tumors in newborns and infants has evolved rapidly in the treatment of both benign and malignant disorders. Newborns and infants with these disorders present with a unique set of problems without parallel in other age groups. As many of these pathologies are so rare, international intergroup collaborations are crucial to foster continued progress and help develop novel therapeutic approaches in managing these disorders.

Congenital mesoblastic nephroma and Wilms tumor

PHILIP J. HAMMOND AND ROBERT CARACHI

INTRODUCTION

Congenital mesoblastic nephroma (CMN), first described by Kastner in 1921,[1] is the most common renal tumor in the neonate, although rare cases present in later childhood. It is also known as a fetal renal hamartoma, mesenchymal hamartoma of infancy, or lipomyomatous hamartoma. It has an incidence of 2.8% of all renal tumors of childhood, with a mean age of presentation of 3.4 months, in contrast to an average age of 3 years in Wilms tumors.[2] It has been documented as being 22.8% of all primary tumors in children 1 year old or less.[3] A neoplasm in the kidney of a child less than 3 months old is usually a CMN. The majority of renal neoplasms originating in the fetus and found during the first weeks of life differ in structure and in biological behavior from a nephroblastoma. In contrast to cystic lesions of the kidney, solid renal neoplasms are rare in the newborn and account for only 8% of neonatal tumors. In the Children's Cancer Group (CCG) neonatal study, there were 25 neonatal renal neoplasms, of which 17 were CMN and the rest were Wilms tumors.[4] A review of neonatal Wilms tumors in the national Wilms tumor register identified 15 cases out of 6832 patients with an incidence of 0.16%, demonstrating how rare malignant renal neoplasms are in neonates. Although prenatal ultrasound is capable of detecting renal neoplasms in utero, there is no specific sonographic characteristic that can differentiate a CMN from a Wilms tumor. Both tumors present as a palpable abdominal mass in the neonate. Males outnumber females two to one with CMN, and both sexes are equally affected by Wilms tumors.

PATHOLOGY AND CYTOGENETICS

Bolande and associates,[5] in 1967, recognized CMN as a unique lesion that could be distinguished clinically and pathologically from true congenital Wilms tumor by its benign clinical behavior, a preponderance of mesenchymal derivatives, and lack of the malignant epithelial components typical of Wilms tumor. A definite infiltrative tendency distinguishes CMN from hamartomas with more limited growth potential. CMN is usually solid and unilateral and can attain a very large size like a uterine fibroid.

Histological differentiation is that of a spindle cell neoplasm with interlacing bundles of fibroblasts and myofibroblasts. Tumor types have irregular interdigitating margins in the perirenal fat, and wide margins of excision are desirable for complete removal. Incomplete removal results in tumor recurrence, which happens within a year of resection in most instances. No chemotherapy or radiotherapy is indicated here, and a wide surgical resection is the treatment of choice.[6]

Atypical and more aggressive mesoblastic nephromas tend to be soft, fleshy tumors with areas of gross hemorrhage and necrosis and are more cellular without recognizable normal glomeruli or tubules.

Another variant is congenital cystic mesoblastic nephroma (cellular variant), which can present as a unilocular hemorrhagic cyst. This can be detected antenatally and misdiagnosed as a hemorrhage into the kidney. The lining of the wall of this cyst shows a typical cellular rim comprising mitotically active small round and spindle-shaped cells, giving the diagnosis of CMN.[7] The treatment for this tumor is surgical.

Gaillard and colleagues[8] recently reported pathological and molecular characteristics of CMN in 35 cases. Based on cellular criteria, 14 were classified as classical, 4 as partly cellular, and 17 as cellular CMN. The mean ages were 24, 11, and 70 days, respectively. There were 13 intrarenal tumors (stage I), but 9 classical, 3 partly cellular, and 5 cellular CMNs extended to the perirenal fat (stage II), and 5 cellular tumors ruptured (stage III). In order to assess cellular proliferative activity, silver staining of nucleolar organizer region (Ag-NOR) proteins was performed on 19 CMNs. The number of Ag-NOR dots per cell was significantly lower in classical and partly cellular CMN than in cellular CMN,

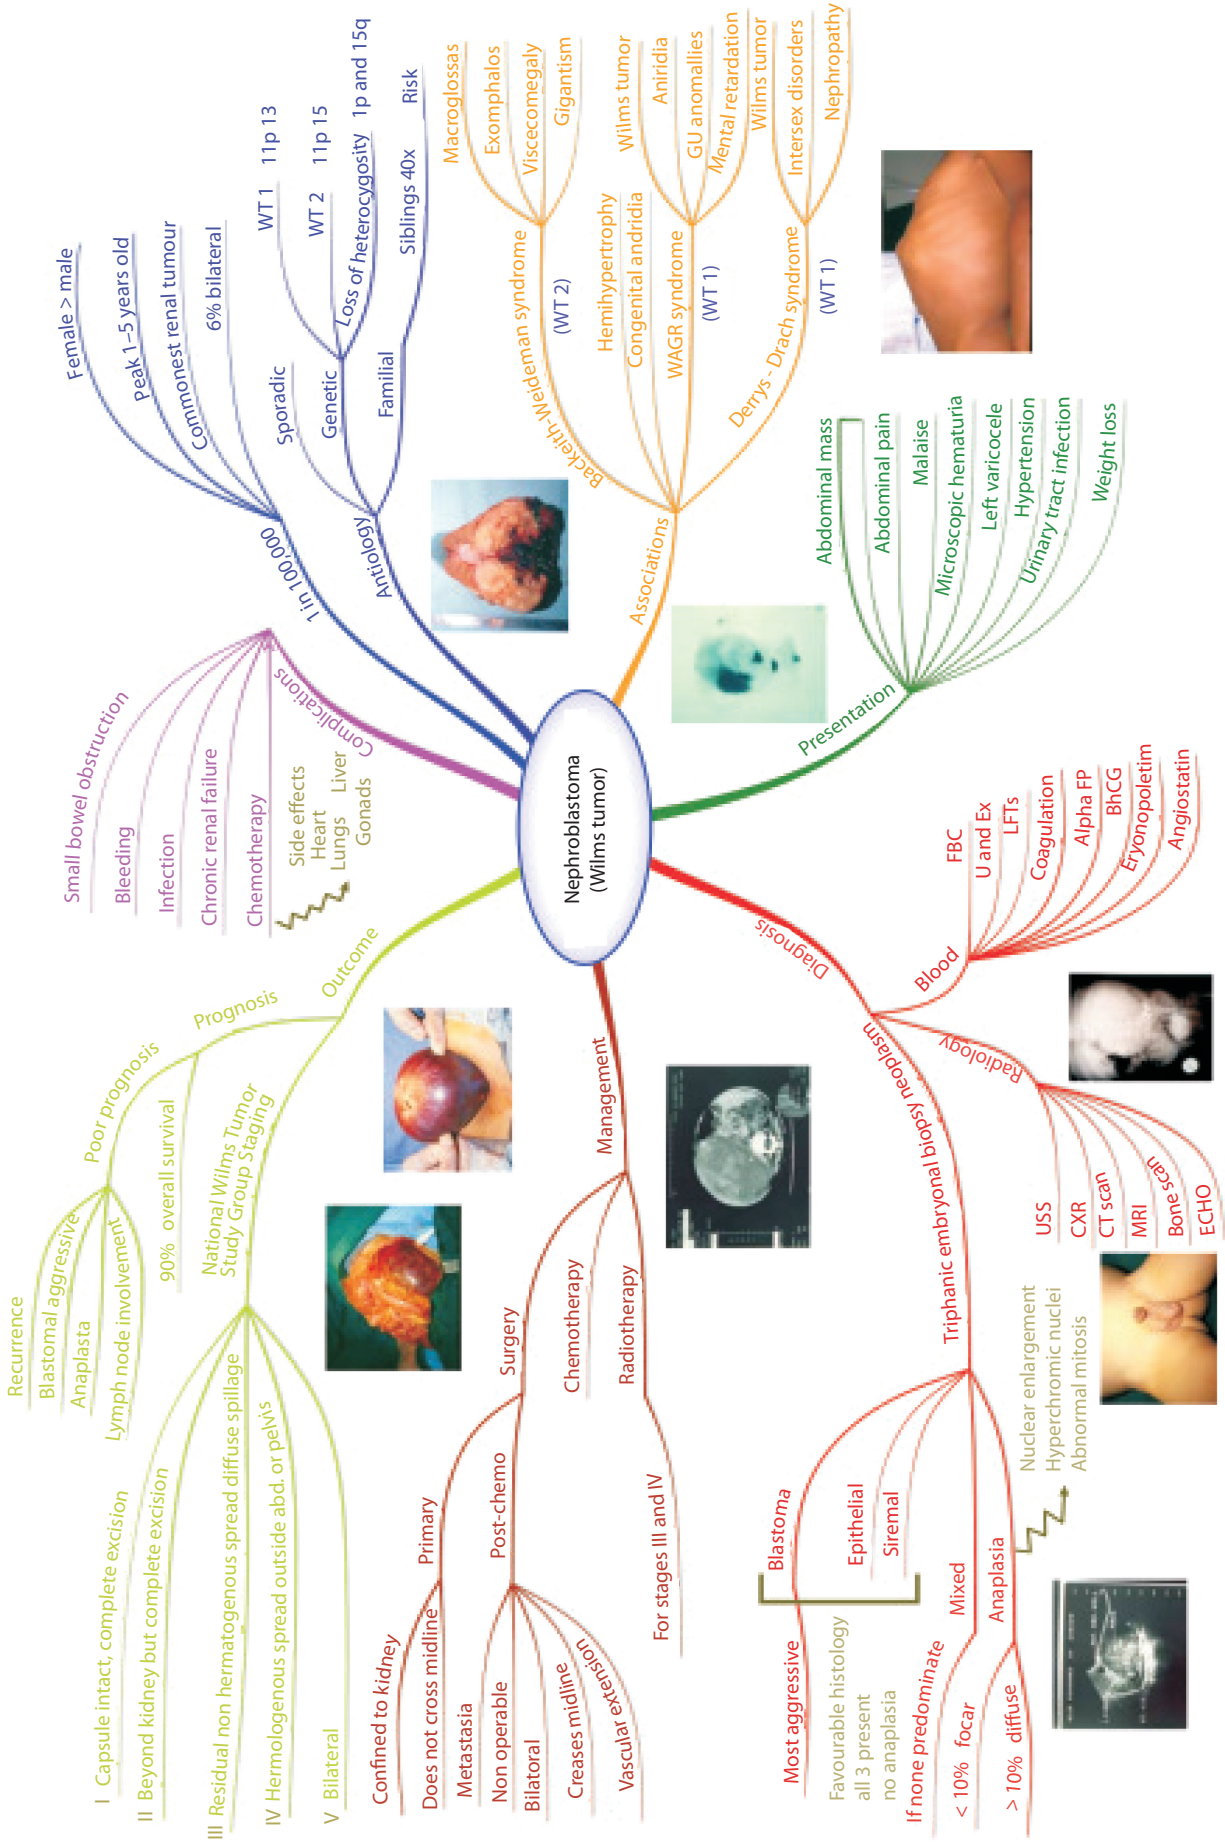

Figure 94.1 Mind map. (From *Practical Problems in Pediatric Surgery—An Atlas and Mind Maps*, Eds. R. Keilani et al., Jaypee Brothers, ISBN 978 81 8448 723 7.)

whatever the stage. Within the cellular CMNs, the mean number of Ag-NOR dots was statistically higher in the single case that recurred with fatal outcome. The number of Ag-NOR dots, DNA content measurements, the histological subclassification, and the presence or absence of tumor at the surgical margins may be useful features in selecting those patients who will benefit from further treatment after nephrectomy.

A characteristic chromosomal translocation, t(12;15)(p13;q25), has been described that results in fusion of the ETV6 (TEL) gene from 12p13 with the NRTK3 neurtrophin-3 receptor gene (TRKC) from 15q25. This results in a chimeric RNA, which is characteristic of both infantile fibrosarcoma and the cellular variant of congenital meroblastic nephroma. This suggests a close relation between these two conditions.[9]

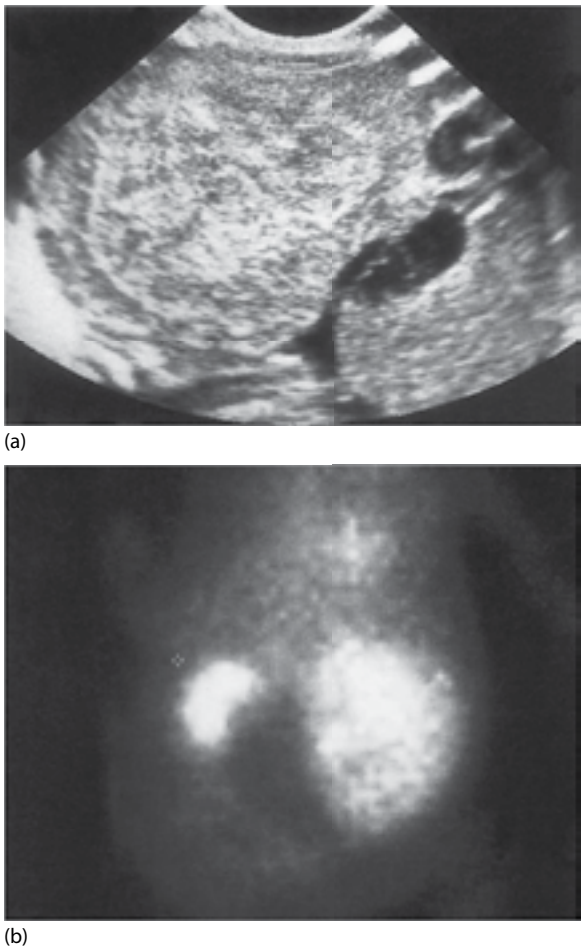
Human epidermal growth factor receptors (HER) play a critical role in the branching morphogenesis of renal tubules. In addition, HER2 expression in Wilms tumor has been assessed, and its role in tumorgenesis has been established. Amplification and overexpression increase the metastatic potential of a tumor and promote chemoresistance.[10]

It has been reported that abnormal renin production and hypertension are common features of CMN. Several investigators have reported distinctive patterns of immunoreactive renin staining, suggesting that mesoblastic nephromas are a source of increased renin production, producing hypertension.[11,12] The most intense staining for renin was observed within areas of recognizable cortex trapped within the tumor. Renin was localized in cells in the walls of vessels running up to the glomeruli.

CLINICAL FEATURES

The newborn usually presents with a large, nontender abdominal mass. Maternal polyhydramnios and prematurity are frequently seen, although the reason for this is unclear. Male-to-female ratio ranges from 1.8:1 to 3:1.[6,12] Hypertension has been recognized as a presenting feature, and there is an association between preoperative hypertension and cardiac arrest during surgery.[6] Some patients present with hematuria. In the congenital cystic mesoblastic nephroma variant, the patient may present with a hemorrhagic problem. Recently, mind maps have been introduced to explain in a didactic fashion the clinical features, investigations, differential diagnosis, and management of CMN and Wilms tumor (Figure 94.1).

Detailed antenatal ultrasound scans may pick up a solid tumor of the kidney. Plain films of the abdomen show a large, soft-tissue abdominal mass that is rarely calcified. Sonography demonstrates the solid nature and renal origin of the mass and most commonly shows a mixed echogenic intrarenal mass (Figure 94.2a and b). CMN should easily be distinguished from more common renal masses in the newborn[13]—hydronephrosis or multicystic kidney—which are sonolucent. Magnetic resonance imaging (MRI) scans give detailed imaging of the renal tumor and its surrounding structures.



(a)

(b)

Figure 94.2 **(a)** Sonography demonstrates a mixed echogenic mass. **(b)** ^{99m}Tc-DTPA renal scintigraphy shows function within the mass in the kidney.

TREATMENT

Nephrectomy of this benign tumor is curative without the need for supplementary radiation or adjuvant chemotherapy. Even when there has been intraoperative rupture, excisional surgery is curative, and local recurrence is rare. Distant metastasis has been reported but is extremely uncommon.[14] A review of 38 patients with the cellular variant of mesoblastic nephroma showed that 7 children had recurrence and 3 died. According to them, pathologically positive surgical margins were the only statistically significant predictor of recurrent disease. Frozen section may help in obtaining tumor-free margins during surgery. Recent studies on molecular biology may shed further light on tumor behavior and add criteria for further therapy after surgery.

PREOPERATIVE PREPARATION

Blood samples are obtained for a full blood count, group, and crossmatch. Tumor markers renin, active renin, and inactive renin should also be assayed because these tumors

have been documented as producing high levels of these hormones.[12] Erythropoietin levels should also be assayed. Careful monitoring and control of blood pressure is required to prevent dangerous perioperative fluctuations. A central venous cannula for intravenous infusion is inserted into the neck vein or subclavian vein as well as an arterial cannula to monitor blood pressure.

OPERATIVE TECHNIQUE

Position

The patient is placed supine with a roll under the lumbar spine to create a lordosis.

Incision

An upper transverse muscle-cutting incision from the flank across the midline provides adequate exposure (Figure 94.3a).

LAPAROTOMY AND EXPOSURE OF THE RENAL PEDICLE

The abdomen is entered, taking care not to cut into the tumor while incising the abdominal wall muscles. The small intestine is displaced toward the opposite side and covered with moist packs. The liver and the opposite kidney are inspected for the presence of any other disease. This is very rare in this condition. Free fluid is sampled and sent for cytology.

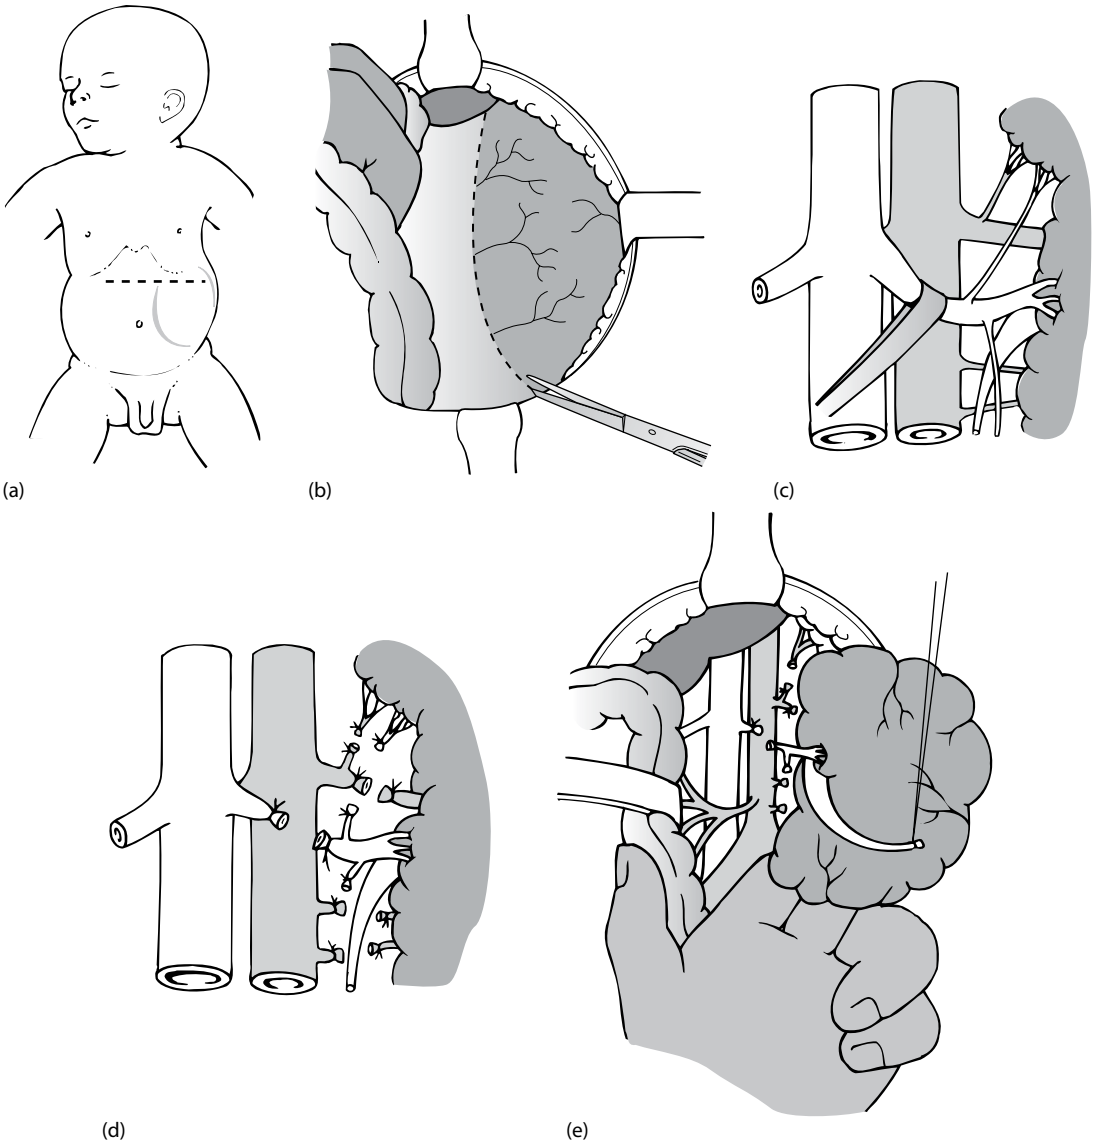


Figure 94.3 Resection of left mesoblastic nephroma: **(a)** incision; **(b)** colon retracted medially and posterior peritoneum incised; **(c)** ureter, gonadal vessels, and renal vessels identified; **(d)** ureter and gonadal vessels ligated and divided—followed by ligation and division of renal vein and artery; **(e)** tumor removed from the posterior abdominal wall using sharp and blunt dissection.

The colon overlying the tumor is retracted medially, and the posterior peritoneum lateral to the colon is incised and reflected forward to the midline (Figure 94.3b). Tumor handling should be minimized in hypertensive patients to prevent excessive release of renin. The inferior vena cava and renal veins are both palpated for the presence of tumor. The ureter is identified (Figure 94.3c), and a tape is passed around it. It is traced as far down as possible into the pelvis, ligated with 3-0 chromic catgut, and divided. Next, the gonadal vessels are ligated and divided. Before mobilization of the tumor, abdominal packs are used to isolate the operative site from the rest of the abdominal cavity. This is to prevent any dissemination of tumor if there is spillage during the time of surgery. The renal vein is doubly ligated and divided (Figure 94.3d). The renal artery is exposed and transfixed with nonabsorbable sutures. The para-aortic lymph glands, together with surrounding tissue, are dissected off the aorta and inferior vena cava and labeled carefully. The tumor is removed from the posterior abdominal wall using finger dissection (Figure 94.3e). The excised specimen should contain the kidney, Gerota fascia, fat from the lumbar fossa, and para-aortic lymph glands.

After removal of the tumor, hemostasis is obtained with diathermy coagulation or suture ligatures. No drainage is usually required.

POSTOPERATIVE CARE

Postoperative recovery following resection of mesoblastic nephroma is rapid. Nephrectomy of this benign tumor is curative. If on histology, the tumor is found to be Wilms, it should be treated in accordance with the degree of involvement as outlined in the National Wilms Tumor Study programs.

COMPLICATIONS

The main complication of CMN is rupture of the tumor during surgery. Howell and colleagues[6] reported intraoperative rupture in 20% of their cases. In practice, this is extremely rare despite intraoperative rupture; excellent subsequent relapse-free survival has been reported with this tumor.

Neonatal ovarian masses

RACHAEL L. POLIS, MARY E. FALLAT, AND CHAD WIESENAUER

INTRODUCTION

Ultrasound examination, both pre- and postnatal, has made it possible for clinicians to recognize perinatal ovarian cysts and other intra-abdominal masses for decades. True neoplasms are rare, simple ovarian cysts are common, and large or complex cysts often demand surgical attention. A variety of approaches including aspiration (both pre- and postnatal), surgical removal, or observation have been proposed and are acceptable depending on the radiographic and clinical circumstances.

ETIOLOGY

Although not fully understood, it is widely believed that ovarian cysts derive from ovarian follicles. Mature follicles can be found in up to 60% of newborn ovaries. Fetal follicle-stimulating hormone (FSH), fetal luteinizing hormone (LH), estrogens (maternal, placental and fetal), and placental human chorionic gonadotropin (HCG) all stimulate the ovarian follicle.[1–3] There is a higher incidence of larger ovarian cysts in infants born to mothers with diabetes, Rh isoimmunization, and preeclampsia due to the association with higher releases of placental chorionic gonadotropin.[4] Akin et al.[5] reviewed 20 cases of ovarian cysts diagnosed antenatally and 5 mothers had gestational diabetes, 2 had preeclampsia, 1 patient had Rh incompatibility without hydrops, and polyhydramnios was present in all cases. Follicular cysts have also been described in maternal and congenital hypothyroidism secondary to nonspecific pituitary glycoprotein hormone synthesis.[4]

At birth, HCG and estrogen levels fall precipitously, leaving only the fetal pituitary gonadotropins LH and FSH to stimulate or maintain the ovarian follicle. The newborn hypothalamus and pituitary become sensitive to negative feedback by about 4–6 months of age, decreasing secretion of LH and FSH. By this time, most if not all stimulation of the ovarian follicle halts, and fetal cysts should involute. Simple ovarian cysts are known to resolve spontaneously in most cases by 1–6 months.[1,6–8]

An alternative theory has been proposed by Enriquez et al.[9] in which abnormal development of the primitive gonad, and not just hormonal stimulation, is the root cause of fetal cyst formation. Cyst formation becomes a consequence of germinal epithelial secretion in a dysgenetic gonad. The prevalence of ovarian cysts would argue against this being the primary mechanism.

Incidence

The normal newborn ovary will exhibit several scattered anechoic cysts from 4 to 5 mm in diameter. More than 80% of newborn ovaries will have ovarian cysts <9 mm in diameter, whereas cysts >9 mm occur in 20%–34% of ovaries.[10] There is general consensus that newborn cysts less than 2 cm in maximal diameter are considered normal and unlikely to cause problems.[1,5]

Torsion

Torsion is believed to occur when a relatively large, mobile mass twists on a long, thin pedicle. Many authors consider cysts of diameter greater than 4 or 5 cm at high risk for complications, most commonly torsion.[1,6–8,10–12] Other authors use a more conservative diameter of 2.0 cm to direct management.[13] Complex heterogeneous ovarian cysts are more likely to represent torsion of the cyst and the ovary, and autoamputation is possible.[13–15]

PATHOLOGY

Pathologic examination, possible only if surgical removal is performed, will often confirm the diagnosis of an ovarian cyst. The vast majority of cysts are of follicular origin. Torsed ovaries will have suffered a variable period of ischemia, so examination may not reveal any identifiable ovarian follicles or parenchyma. Tumors are rare in the

newborn, but careful examination of the literature reveals examples. In what appears to be the most extensive review in the English language of 257 antenatally diagnosed ovarian cysts, Brandt et al.[1] reported 3 cystadenomas and 2 teratomas out of 170 surgically removed ovaries. Three other authors have reported antenatally diagnosed tumors including two germ cell tumors, one teratoma, and one serous cystadenoma.[13,16,17] There exist two reports of ovarian carcinomas found at fetal autopsy. These were bilateral ovarian cancer in a 30-week gestation fetus, and a granulosa cell carcinoma in a stillborn fetus.[18,19] Juvenile granulosa cell tumor, a tumor that may be considered malignant due to its aggressive potential, is described in children less than 7 months of age in three reports.[20–22] Finally, there exist reports of one endodermal sinus tumor and one teratoma in children under 1 year of age.[23]

HISTORY AND PHYSICAL EXAMINATION

Most newborns with ovarian cysts will have a normal physical examination at birth. Since the ovary is an intra-abdominal organ in an infant, large cysts will displace the intestinal tract and present as palpable, but generally non-tender, masses. These infants rarely have signs of intestinal obstruction or hydronephrosis due to compression of the ureters if the mass reaches substantial size.[5]

PRESENTATION

Most neonatal ovarian cysts are first diagnosed at prenatal ultrasound. Their appearance is almost exclusively in the third trimester, at around 28 weeks gestational age.

DIAGNOSIS

Ultrasound is the modality of choice for both the infant and the mother, being quick, relatively inexpensive, and safe, compared to other imaging modalities. Magnetic resonance imaging has been proposed as more reliable by some authors,[24] but discounted by others,[25] based on expense and potential need for sedation. The basic criteria for ultrasound diagnosis are as follows: (1) cystic structure in the lower or lateral abdomen and (2) normal urinary and gastrointestinal tracts.[25] Differential diagnoses include urachal cyst, enteric duplication, hydrometrocolpos, choledochal cyst, renal cyst, hydronephrosis, distended bladder, meconium cyst, duodenal atresia, anterior myelomeningocele, mesenteric cyst, lymphangioma, and omental cyst, with the latter three entities being the most easily confused with ovarian cyst.[1,8,26,27]

Nussbaum et al.[28] proposed useful criteria for simple and complex ovarian cysts in 1988. Simple cysts are completely anechoic with an imperceptible cyst wall (Figure 95.1), whereas complex cysts demonstrate a fluid/debris level, have a retracting clot, are septated, or are solid (Figure 95.2). The presence of a complex heterogenous ovarian cyst with a fluid debris level can be a hallmark of ovarian torsion. Of all "complex" cysts, Monnery-Noché et al.[13] found 89% to be torsed, with the remainder being hemorrhagic. Diagnosis or suspicion of an autoamputated ovarian cyst can be guided by the appearance of the cystic mass in different positions on postnatal ultrasound compared to prenatal ultrasound or the presence of calcifications within the cyst identified on imaging.[14]

Evolution

Prenatal and postpartum sonographic observation has allowed investigators to determine the behavior of ovarian cysts, although predictions vary by author. Anywhere from 44% to 70% of antenatally diagnosed simple cysts will convert to complex, presumably by torsion, by the time of the first postpartum ultrasound.[8,13,29–31] Five studies published between 1992 and 2008 considered simple cysts of all diameters. Some authors have correlated antenatal cyst size with risk of ovarian loss,[1,6,11] but more recent investigations have demonstrated no correlation between size and risk of ovarian loss.[13,29,30,32] The latter studies call into question the usefulness of cyst diameter in surgical decision-making.

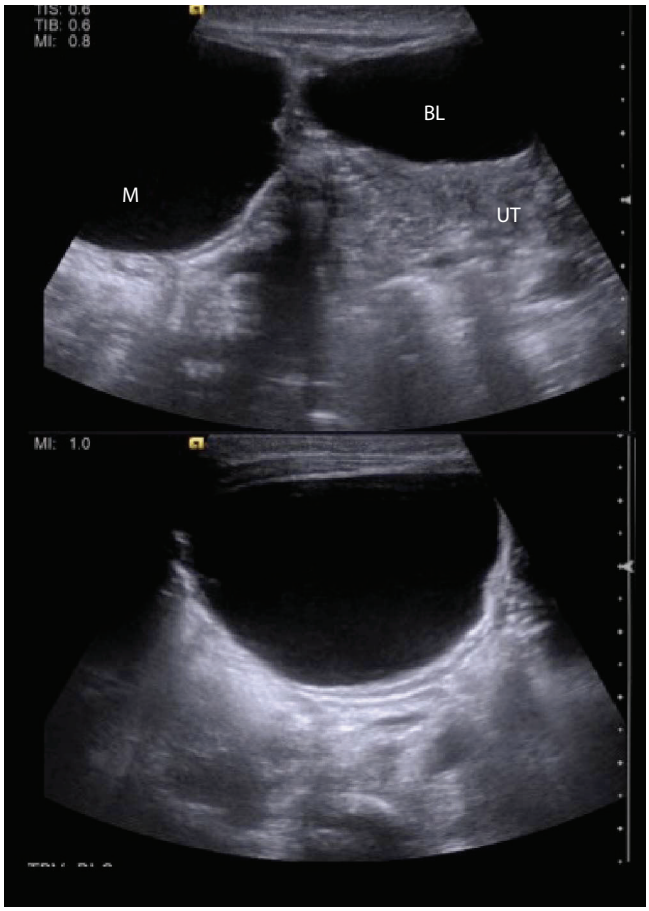

Figure 95.1 Top: Transabdominal ultrasound on day 1 of life (M = mass, BL = bladder, UT = uterus). Bottom: Same transabdominal ultrasound study with mass identified as a simple ovarian cyst measuring 4.8×3.2×4.7 cm. There is a lack of internal echoes and no perceptible cyst wall.

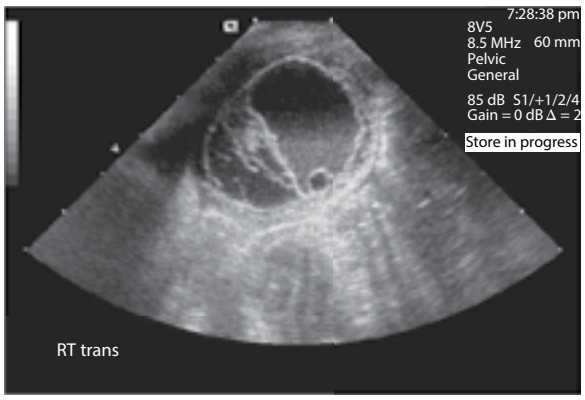

Figure 95.2 Transabdominal ultrasound of a complex ovarian cyst, 2.5 cm × 3.5 cm. Features include a relatively thick cyst wall, fluid/debris level, and multiple septations. This ovary was found to be torsed and nonviable.

Somewhat in dispute of the above prediction, simple cysts (all diameters) are also known to regress spontaneously postpartum in at least 82% of cases.[8,31] Sakala et al.[33] cite 50% resolution by 1 month, 75% by 2 months, and 90% resolution by 3 months. The remainder of these simple cysts are generally aspirated or operated upon for failure to regress in size after a period of observation.

Concerning complex cysts, three studies included 45 patients observed using serial postpartum ultrasound examinations.[8,30,31] Twenty-two followed complex cysts demonstrated regression of both the cyst and ovary at subsequent follow-up ultrasounds. Surgical removal of 15 ovaries was performed, 13 due to failed regression and 2 due to parental concern. Only eight ovaries demonstrated both cyst regression and detectable ovarian tissue.[8,30,31] Both Luzzatto et al.[8] and Foley et al.[30] noted that this occurred before 1 year of life. In cases where the complex cyst involuted and a viable ovary was not subsequently seen, it may be speculated that the gonad was torsed and necrotic and eventually resorbed spontaneously. More reports are needed to know if observation in these cases is a legitimate therapeutic option.

MANAGEMENT

The treatment of newborn ovarian cysts remains controversial. Considering only simple cysts, the majority of authors still selectively operate or aspirate (including in utero aspiration) based on a maximal diameter of 4 or 5 cm,[1,8,10,12,34–36] although other authors support close ultrasound observation for larger simple cysts with good results.[26,29,31]

As for complex cysts, a growing number of authors support ultrasound observation, with surgical treatment only if they fail to demonstrate continuous regression over time.[8,9,26,29–31,37,38] Other surgeons prefer to definitively exclude malignancy by removal of the complex ovarian cyst.[1,3,12,35] In a retrospective chart review from Papic et al.,[38] 25 asymptomatic cysts were observed including 15 complex cysts, and 6 of these had successful regression. The mean size of successfully observed complex cysts was 41 ± 16.1 mm.[38] When failure of cyst regression occurred, the mean observation time prior to surgery was 12 weeks.[38] Complex cysts measuring ≤58 mm have been observed in the literature.[8] These complex cysts followed by ultrasonography have documented regression.[8] However, there are documented cases where no viable ovarian tissue can be identified on follow-up ultrasound imaging.[8,30,31,37] As complex cysts generally represent ovarian torsion as well, surgery would inevitably result in oophorectomy. Therefore, considering observation when ovarian regression is a possibility could preclude neonatal surgery. In a study by Papic et al.,[38] a period of observation spared about half of neonates an operation, which has relevance based on emerging data that anesthesia in the newborn period may have adverse effects on the developing brain.[39–41] See Table 95.1 for risks and benefits of early operative intervention versus observation.

Neonatal anesthesia risks

Experimental studies in animals demonstrate that exposure of the brain to a variety of anesthetic agents during developmental periods can lead to neurodegeneration or neuronal apoptosis and cause measurable functional deficits.[42–48] Flick et al.[49] concluded that exposure to multiple episodes of anesthesia, particularly during multiple surgical procedures, before the age of 2 significantly increased the risk of learning disabilities. A systematic review and meta-analysis conducted in January 2000 through February 2013 suggests a modestly elevated risk of adverse neurodevelopmental outcomes in children when exposed to anesthesia early in childhood.[40] There is a need for large, prospective observational studies and trials to investigate anesthesia effects on the developing human brain,[50] and further research is being done. It is important for clinicians to weigh the potential anesthesia risks into their management plan. Figure 95.3 outlines a surgical treatment strategy for neonatal patients with ovarian cysts modified from a study by Tajiri et al.[36]

In utero aspiration

To avoid the above-cited 44%–70% risk of in utero torsion of the simple cyst, some investigators have attempted in utero decompression.[51] Perrotin et al.[51] successfully aspirated three in utero simple cysts between 37 and 47 mm. Bagolan et al.[35] appear to have published the largest series of 14 patients without a direct technical complication in cysts measuring ≥5 cm. Of note, Bagolan et al. reported two errant prenatal diagnoses among their in utero aspirations. These masses were both hydronephrosis, and both fetuses suffered no untoward effects from these aspirations. Some would argue that these were actually technical complications.[35] Two ovaries torsed despite aspiration, making the ovarian preservation rate 86%, which is better than historic controls; however, the number of patients is small.[35] There are no recent published studies to date further investigating if in utero aspiration continues to be a viable option for management.

Table 95.1 Risks and benefits of intervention or observation

Cyst aspiration		Operative management		Observation	
Risks	**Benefits**	**Risks**	**Benefits**	**Risks**	**Benefits**
1. Potential of multiple aspirations if cyst recurs with associated repeated exposure to anesthesia.	1. Potential ovarian preservation.	1. Future adverse neurodevelopmental outcomes secondary to anesthesia exposure.	1. Definitive diagnosis with specimen.	1. Ovarian torsion.	1. Cyst resolves spontaneously.
2. Extended follow-up is rare and preservation of future viable ovarian tissue unknown.	2. Shorter and less invasive procedure.	2. Ovarian tissue loss due to oophorectomy.	2. Direct visualization of ovary.	2. Surgical intervention needed at a later date.	2. Avoids unnecessary surgery and exposure to anesthesia.
3. Incorrect diagnosis of an ovarian cyst with aspiration and injury to another organ system.			3. Early intervention might preclude torsion and spare ovary.	3. Patient fails to come back for follow-up. 4. No identifiable ovarian tissue on the involved side in the future.	3. Ovarian preservation.

Dera-Szymanowska et al.[52] presented a recent case report of notable recurrent complex ovarian cysts with rupture in the fetal period and recurrence of simple cysts in the neonatal period. This group suggested surgical intervention be considered postnatally and only with symptoms or in complicated cases.[52]

Postnatal aspiration

Proponents of postnatal aspiration point to maximal preservation of ovarian tissue coupled with cyst decompression to potentially prevent torsion. Also, many authors mention that the majority of operatively managed ovarian cysts involve oophorectomy, not cystectomy or fenestration, thereby removing any chance of viable ovarian tissue on the affected side. Opponents point out lack of a definitive diagnosis, i.e., risk of cancer. Kessler et al.[10] reported 17 aspirated ovarian cysts, both simple *and* complex, with a 67% ovarian preservation rate. No complications were reported, although three cysts recurred and responded to repeat aspiration. Other investigators have had similar success,[12] yet Puligandla et al. report a case whereby a proximal jejunal duplicated cyst was mistaken for ovarian pathology and aspirated. The patient was later found to have necrotic bowel secondary to a midgut volvulus, and she ultimately died.[53] Finally, Tajiri et al.[36] reported 13 cases of ultrasound-guided aspiration of cysts, one patient treated with aspiration three times, and another undergoing the procedure twice. All 13 cases eventually had no remaining cystic lesions.[36] There was no description provided about the presence of ovarian tissue on subsequent imaging after ultrasound-guided cyst aspiration, so there may be morbidity related to the procedure itself that no one has looked for or reported.

Operative removal

The majority of large simple cysts and complex cysts are removed via laparotomy or laparoscopy. A large cyst is defined as greater than either 4 or 5 cm in maximal diameter, although at least one group operatively removed simple cysts greater than 2 cm in diameter.[13] Although the goal is always ovarian tissue preservation, more often than not, the entire ovary is removed for lack of identifiable ovarian parenchyma.[2,9,10,19,23,29,33] Fenestration of the cyst wall is an option if the cyst wall cannot safely be entirely separated from ovarian tissue. Proponents of operative removal cite this as the only method to exclude neoplasia, and also the only method that results in no chance of viable ovarian tissue on the affected side. They also cite risk of adhesive bowel obstruction as a potential complication of unremoved ovarian cysts, although this is not described even in case reports.[2,3,13]

Surgeons have come up with many creative alternatives to suprapubic laparotomy (Figure 95.4), including

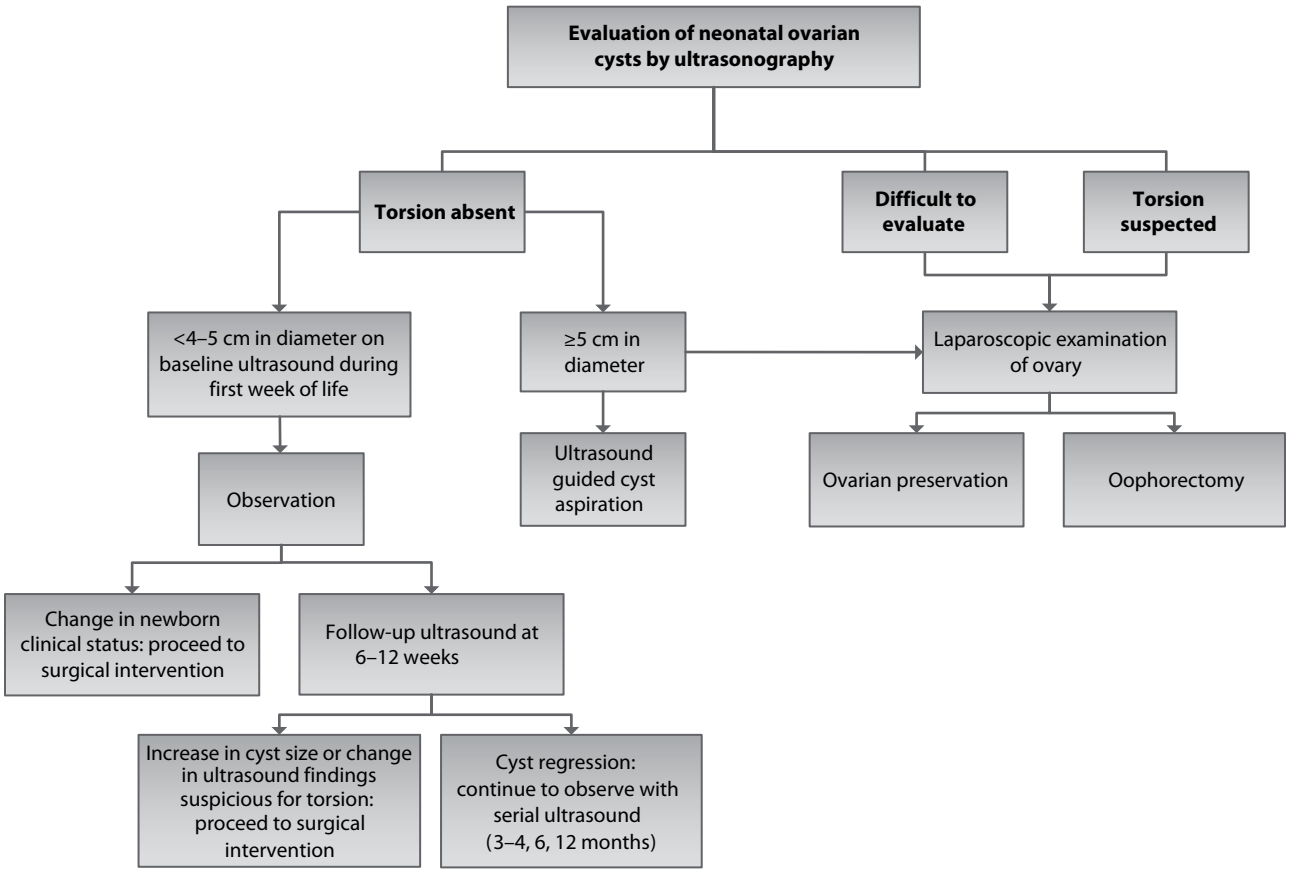

Figure 95.3 Management strategy for neonatal ovarian cysts.

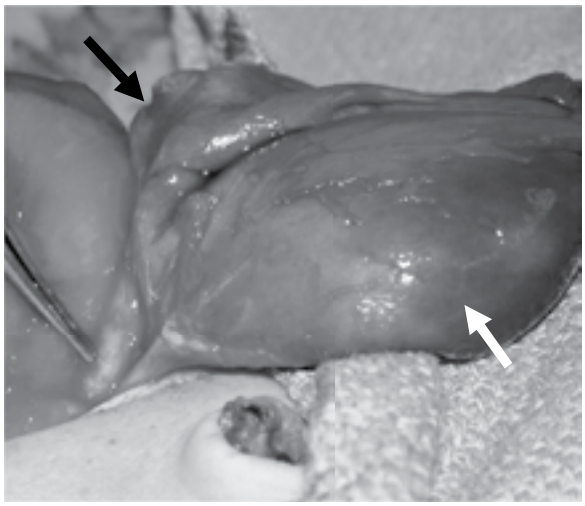

Figure 95.4 Torsed ovary with large attached cyst, exteriorized via a suprapubic transverse incision. White arrow points to cyst, black arrow points to torsed and nonviable right ovary, and forceps points to healthy uterus. Viable left ovary and tube are to the left of uterus.

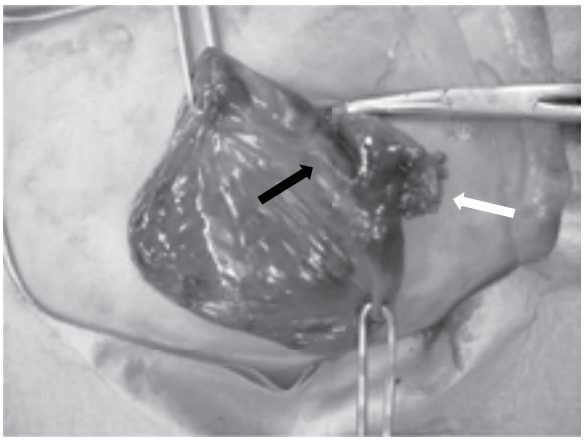

Figure 95.5 Simple ovarian cyst drained and exteriorized via umbilical incision. White arrow points to fallopian tube, black arrow to ovarian parenchyma and follicles near the blood supply of the ovary. The parenchyma is splayed out over the cyst. The cyst wall can be fenestrated or removed if it easily dissects free from the ovary.

exteriorization–aspiration, transumbilical removal (Figure 95.5), and modifications using the laparoscopic approach.[54–59] Laparoscopy is a safe and reliable treatment of ovarian cysts in the neonatal period.[59,60] If done laparoscopically, fenestration may be easier than cystectomy to avoid removing ovarian tissue unless the ovary has torsed and is necrotic. If done open, an ovarian-sparing cystectomy can be facilitated by injecting saline in the interface between the cyst and the ovary, using a scalpel or electrocautery to begin the dissection, and then the cyst can often be peeled off the surface of the ovary using a moist

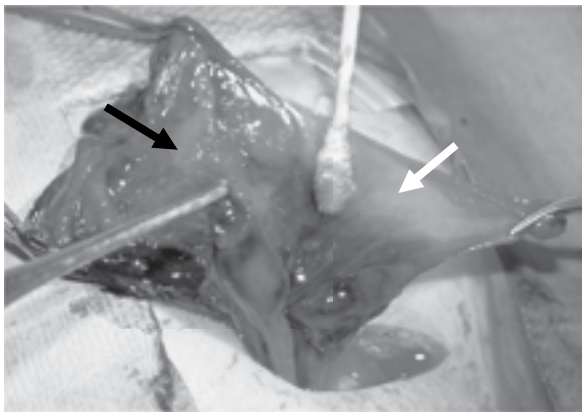

Figure 95.6 Dissection of ovarian cyst from ovarian tissue using a cotton-tipped applicator. White arrow points to cyst wall, black arrow points to ovarian parenchyma, and forceps hold fallopian tube. Despite ischemia, it is still worthwhile to spare the ovary if possible. Some tissue will atrophy, but there also may be viable ovary that will survive. It is not necessary to completely remove the cyst wall; a specimen can be sent to pathology in formalin.

cotton-tipped dissector or swab to facilitate the dissection (Figure 95.6). Subsequent bleeding at the ovarian surface can be controlled using electrocautery. It is not necessary to reapproximate ovarian tissue, but an absorbable small gauge suture should be used if this is felt necessary.

COMPLICATIONS

Complications of cyst observation include a missed malignancy, although this is very rare. As stated above, some authors believe that torsed, necrotic ovaries have the potential to cause adhesive bowel obstruction. Complications of cyst aspiration include misdiagnosis and any consequences of unintentional needle injury to another organ. Complications of operative removal include injury to viable ovarian tissue that might have been functional without intervention, and also the risk of adhesive bowel obstruction inherent to any transabdominal operation.

LONG-TERM RESULTS

Cesca et al.[37] investigated 41 neonates with congenital complex ovarian cysts managed conservatively with an average diameter of 4.16 ± 1.11 cm. Long-term follow-up was completed in 10 of the 41 patients at the mean age of 12 years, and no cyst recurrence or complications after cyst resolution were identified.[37]

No long-term studies to date have examined future fertility in the population of newborns and infants who had ovarian cysts or tumors subjected to a variety of therapeutic options.

Spina bifida and encephalocele

JOTHY KANDASAMY, MARK A. HUGHES, AND CONOR L. MALLUCCI

INTRODUCTION

Neural tube defects (NTDs) encompass a variety of congenital anomalies ranging from anencephaly to spina bifida occulta, and arise due to defects in the morphogenesis of the neural tube. While spina bifida remains the most common congenital central nervous defect encountered in neurosurgical practice, the overall incidence of NTDs is in decline.[1–4] Multiple factors account for this change, including increased antenatal diagnosis, declining birth rates, changing social attitudes, and improved standard of living and diet. A diagnosis of spina bifida can have devastating consequences, and the "correct" management of these patients is a continued source of medical, ethical, and legal controversy. A multidisciplinary team is required, including neurosurgeons, pediatricians, neurologists, urologists, orthopedic surgeons, physiotherapists, social workers, psychologists, and nursing staff. At the center are the patient and family, with the common goal being social integration and a meaningful life.

HISTORY

Caspar Baulinin is credited with the first accurate description of spina bifida in the early seventeenth century.[5] The term *spina dorsi bifida* was coined by Nicholas Talpius (Tulp) in 1641,[6,7] and Virchow[8] introduced the term *spina bifida occulta* in 1875. The association of hydrocephalus and spina bifida was recognized by Morgagni[5] in 1761. He also described anencephaly and spina bifida as expressions of the same pathological process, and attributed bladder, rectal, and limb abnormalities to the neuronal damage in the defective spinal cord.

Aspiration of the lesion was the time-honored method of management but had catastrophic consequences. Forestus ligated the sac,[9] and sac excision was attempted by Tulp[7] with fatal results. The Clinical Society of London[9] recommended the use of a local sclerosing technique, which was initially advocated by Morton.[10] Excision of the sac was again popularized by Bayer[11] and Frazier[12] in the early twentieth century, but the mortality rate remained high. With the advent of antibiotics and introduction of cerebrospinal fluid (CSF) shunts in the 1950s, improved operative results encouraged more surgeons to introduce comprehensive, aggressive management. In 1963, Sharrard, Zachary, and Lorber[13] proposed emergency operative closure of the back lesion to decrease mortality and improve muscle function. This provided new hope for these patients, though it became evident that mortality remained high and those who survived had major disabilities. Lorber,[14] who was one of the supporters of the aggressive policy advocated by the Sheffield group, reviewed 524 cases of myelomeningocele treated actively and concluded that there were four main criteria associated with a poor prognosis: gross hydrocephalus, severe paraplegia, kyphosis, and associated gross congenital anomalies or major birth injury. He advised that patients with one or a combination of these criteria should be managed conservatively, as very few patients survived, and those that did would suffer severe mental and physically handicap. In recent years, the reliability and predictive value of these four criteria has been challenged. It has been suggested that management should be more individualized and changed whenever necessary in the best interests of the patient and family.[15–17]

INCIDENCE AND EPIDEMIOLOGY

There are geographic variations in the incidence of spina bifida and NTDs worldwide. For example, the incidence of spina bifida cystica is 0.3 per 1000 live births in Finland but 4.5 per 1000 live births in Ireland.[18] There is greater reported variation in the incidence of spina bifida occulta, which ranges between 1% and 50% depending upon the age group.[19] Caucasians are at higher risk of developing spina bifida[20] than African Caribbean people, and lower socioeconomic groups also seem to have a higher incidence of the defect.[21] Where they occur, public health initiatives promoting folate supplementation have reduced incidence of NTDs.[22] The incidence of spina bifida cystica live births is also influenced by the cultural and social norms of each

society, access to antenatal diagnosis, and counseling as regards pregnancy termination and specific national legal parameters for this.

EMBRYOLOGY

NTDs result from an abnormality in the process of neurulation. The primitive streak and Hensen's nodes are present in the embryo at 2 weeks' gestation. The notochord starts extending rostrally from Hensen's node, and this induces the process of neural tube formation. Thickening of the ectoderm cephalic to Hensen's node occurs and forms the neural plate. Folding and later fusion forms the neural tube. This process continues caudally up to the somites, which start to appear from week 3. Other ectodermal tissue closes over this and buries the tube. The unfused rostral and caudal neural folds are called the anterior and posterior neuropores. These close at about 25 days and 30 days respectively, at which point the process of neurulation is complete. At this stage, there are 21–29 somites. Four somites are incorporated into the occipital bone and 20 in the cervical and thoracic vertebrae. Caudal to this, the remainder of the tube forms the caudal cell mass. During the next 4–5 weeks, canalization of this cell mass occurs, followed by regression of the most caudal part, which forms the filum terminale. The notochord separates from the neural tube dorsally and the gut ventrally, forming subchordal and epichordal spaces.

PATHOGENESIS

All developmental defects of the central nervous system are NTDs. Neurulation defects are a subgroup of NTDs. These defects can involve the following:

1. *Brain*
   Anencephaly: A result of persistence of the anterior neuropore. This allows some part of the developing brain to remain in contact with the amniotic cavity. The types are holocrine, if the defect extends to involve the foramen magnum, and mesoacrania, if the foramen is not involved.[23]
   Encephalocele: The result of defective cephalic neurulation.
2. *Spinal cord*
   Meningocele: A postneurulation defect.
   Myelomeningocele: Defective caudal neurulation results in myelomeningocele, which can occur anywhere from cervical to lumbar sites. There are various theories put forward to explain the precise mechanism of the defective neurulation. These are due to either failure of neural folds to fuse or a reopening of the normally fused neural tube. Defective neuroepithelium itself may be responsible for the failure of neural folds to fuse,[24] or the defect may lie in mesoderm, which deters the closure of neural folds. The normally fused neural tube may reopen because of increased intraluminal pressure[25] or a primary defect in the neuroepithelium.
   Associated Arnold–Chiari malformation may be secondary to failure of ascent of the cord within the spinal column because of tethering or as a result of descent secondary to increased pressure of hydrocephalus.
3. *Brain and spinal cord*
   Craniorachischisis: Where there is failure of neural tube fusion at both brain and spinal cord level.
4. *Other defects*
   Occur secondary to various postneurulation abnormalities involving the neural tube or mesoderm, or because of persistence of totipotent cells. These lesions are diastematomyelia, complete anterior and posterior spina bifida, butterfly vertebrae, lipoma, hemangioma, dermoid cyst, and sacrococcygeal teratoma. A partial duplication and separation of the notochord can result in herniation of the endoderm of the yolk sac, called split notochord syndrome. If the hernia ruptures, it may result in ectopic bowel, sinus, or fistula.[26]

TERMINOLOGY AND CLASSIFICATION

Types of NTDs vary in severity, ranging from anencephaly to spina bifida occulta. These lesions can be classified as shown in Table 96.1. Myelomeningocele is one of the most common congenital malformations.

Spina bifida occulta

The term *spina bifida occulta* refers to spinal dysraphism not accompanied by extrusion of the contents of the vertebral column. Spina bifida occulta, without any external evidence, is rarely diagnosed in the newborn. Occasionally, it may cause neurological deficit because of a tethering of the cord. Some patients may have external evidence of spina bifida occulta, such as a small dimple, sinus, tuft of hair (Figure 96.1), or hamartomatous lesions such as hemangioma, lipoma, or nevi. Neural involvement may manifest as urinary problems, (e.g., recurrent urinary infection or enuresis), motor deficit with pedal deformity, pelvic tilt and muscle weakness, or sensory involvement in the form of trophic ulceration. All these patients warrant careful examination and investigation. Spinal x-ray will show evidence of spina bifida and other spinal abnormalities. Ultrasonography can be useful in the newborn period to diagnose diastomatomyelia.[27] The common clinically relevant lesions are lipomyelomeningocele, tethered cord, dermal sinus tract, and diastematomyelia. All of these lesions warrant craniospinal magnetic resonance imaging (MRI) and referral to a neurosurgical specialist. The increased incidence and treatment of these lesions over the last 10–20 years probably reflects more widespread availability of MRI.

Table 96.1 Classification of neural tube defects

Site	Lesion	Pathology
Craniospinal	Craniorachischisis	Involves brain and spine
Cranial	Anencephaly	Brain and skull poorly developed
	Exencephaly	Exposed brain without skin or bone cover
	Encephalocele	Brain herniation through congenital opening of skull and covered by meninges and skin
Spinal	Spina bifida cystica	Open cord defect at any point from cervical to sacral
	a. Myelomeningocele	Skin-covered sac formed of meninges—defect in posterior arch
	b. Meningocele	
	Spina bifida occulta	Absent spinous process and varying amounts of lamina (may be associated with lipomyelomeningocele, tethered cord, dermal sinus tract, diastematomyelia, hemangioma)

Figure 96.1 Spina bifida occulta. A large tuft of hair over the lumbosacral region in this baby was associated with spina bifida occulta and a tethered cord.

Figure 96.2 Dorsolumbar myelomeningocele. This infant had normal movement in both lower limbs.

Spina bifida cystica: meningocele

A meningocele is an epithelium-lined sac filled with CSF, which communicates with the spinal subarachnoid space. Meningocele, which comprises about 5% of all spina bifida cystica cases, is usually not associated with neurological deficit or hydrocephalus, and is most frequently observed in the lumbar region.

Spina bifida cystica: myelomeningocele

Myelomeningocele is the most common form of NTD (Figure 96.2). A neural plaque is centrally placed, around which there is a cystic lesion with attenuated meninges and skin (Figure 96.3). Although local pathological changes are obvious at the site of the lesion, additional changes may involve the whole of the nervous system and other systems, especially genitourinary and skeletal.

ETIOLOGY

The precise etiology of NTDs is not known, though genetic and environmental factors have been implicated.

Genetics

The exact mode of inheritance is unknown. Ethnic and gender variation (females are more commonly affected), and increased incidence with parental consanguinity and a

Figure 96.3 Myelomeningocele. Lesion showing neural plaque in the center covered by a thin membrane.

familial tendency, suggest a multifactorial hereditary mechanism. If there is one child with spina bifida in the family, the risk of having other children with spina bifida increases to 1 in 20–25.[28,29] This risk increases to 1 in 8–10 if there are two children with NTDs.[29] The risk of having an affected child is less if one of the parents has spina bifida (1 in 200) than if a sibling has spina bifida.[28]

Dietary factors

Substantial data have been accumulated to suggest that myelomeningocele and other neural defects can be reduced by improved maternal nutrition. Mothers of spina bifida patients were found to have an increased incidence of folate metabolism abnormalities.[30] Several studies report a beneficial role of folic acid and other vitamins.[31–34] The Medical Research Council conducted a randomized double-blind prevention trial with factorial design at 33 centers in seven countries to determine whether periconception supplementation with folic acid or a mixture of seven other vitamins (A, D, B_1, B_2, B_6, C, and nicotinamide) could prevent NTDs.[35] This study found a significant reduction in the number of children with NTDs born to high-risk mothers who had taken folic acid in the periconceptional period. Periconception use of folic acid has been recommended to all women, with or without risk. A concern that large doses of folic acid may delay the diagnosis of pernicious anemia has led to the fortification recommendations being limited to a level that may add, on average, only about 0.1 mg folic acid/day. However, others feel that a daily dose of 0.4 mg/day should be continued.[36] Studies from Canada, the United States, Australia, and China have shown a decline in NTDs, especially in high-risk groups, with folic acid supplementation and food fortification.[3,22,37,38]

Teratogens

In utero exposure to some antiepileptic drugs increases the risk of fetal NTDs (6%–16% for sodium valproate[39,40] and 2%–6% for carbamazepine.[41,42] These are often at the severe end of the spectrum and associated with hydrocephalus.[43] Certain viruses[44] and hyperthermia have also been hypothesized to cause NTDs, and exposure to heat in the form of a hot tub, sauna, or fever in the first trimester of pregnancy has also been associated with an increased risk of NTDs.[45–47]

PRENATAL DIAGNOSIS

Prenatal diagnosis of myelomeningocele allows improved obstetric care or termination of an affected fetus.[48]

Alpha-fetoprotein in maternal serum

Alpha-fetoprotein (AFP) can be detected in maternal serum where the fetus has an open NTD. Elevated levels after 16 weeks' pregnancy are suspicious; the test is repeated a week later to confirm the presence or absence of NTDs. The sensitivity of this test is 97% for anencephaly and 72% for spina bifida.[49] This second test requires further confirmation by amniocentesis and prenatal ultrasonography after appropriate counseling.

Ultrasonography

Prenatal ultrasonography may be used as a primary screening procedure. It is a safe and effective method of antenatal screening if the ultrasonographer is experienced[50] (up to 98% specificity and 94% sensitivity).[51] Within Europe, there are formal national ultrasound screening policies for structural anomalies.[52] However, detection rates are influenced by gestational age and type of NTD. Spina bifida has a higher detection rate in the second trimester (92%–95%) compared to the first trimester (44%).[53] Three-dimensional sonography has an advantage over conventional two-dimensional ultrasound in predicting the level of lesion, and this may help to predict morbidity.[53]

Prenatal MRI

While ultrasound is the method of choice for prenatal screening, fetal MRI is a valuable second-line tool.[54] It can help to clarify unclear ultrasound findings and define the extent of confirmed lesions, thereby informing prognosis.

Amniocentesis

Many now question the use of amniocentesis in the era of high-resolution ultrasonography. In selected cases, biochemical analysis of amniotic fluid remains useful.[55] Using

ultrasound guidance, amniotic fluid is obtained transabdominally at about 16 weeks' gestation. AFP and acetylcholinesterase (ACE) levels are measured. If AFP levels are ≥+3 standard deviations (SD) above normal, the risk of open NTD is 60%, rising to 86% if the levels are ≥+5SD above normal. The combined analysis of AFP and ACE in amniotic fluid increases the accuracy of diagnosis.[56]

CLINICAL MANAGEMENT

This section relates primarily to the management of myelomeningocele as this is the most common NTD that presents to pediatric neurosurgical practice.

Prenatal assessment and antenatal counseling

Once a prenatal diagnosis of myelomeningocele has been made, MRI of the fetus is performed to determine the level and extent of defect. This allows the neurosurgeon to predict the likely degree of neurological deficit and facilitates prenatal counseling. Antenatal counseling is undertaken in specialist clinics and involves fetal medicine specialists, obstetricians, neurosurgeons, and radiologists. Parents need to be given realistic expectations regarding prognosis for intellectual development, ambulation, and survival, as well as information on hydrocephalus and neurogenic bowel and bladder.

It remains controversial whether cesarean section should be carried out if a prenatal diagnosis of myelomeningocele has been made. Luthy et al.[57] reported that delivery by cesarean for a fetus with uncomplicated myelomeningocele before onset of labor may result in better motor function than vaginal delivery or cesarean section after labor has commenced. Other authors do not support this.[58] While there is no clear evidence, caesarean section facilitates a timed delivery that allows for planning of surgical closure of the myelomeningocele.[59]

In utero surgery

There is a potential role for fetal surgery for some NTDs. Techniques using endoscopy, using percutaneous fetoscopic patch coverage, and via hysterotomy have been described. The Management of Myelomeningocele Study (MOMS) was a multicenter randomized prospective trial comparing prenatal (18–25 weeks of gestation) and postnatal repair of myelomeningocele. Outcomes assessed include death, the need for ventricular shunting by 1 year of life, and neurological function at 30 months of age. The MOMS study found that prenatal surgery for myelomeningocele reduced the rate of shunting (40% compared with 82%) and improved a composite score of mental development and motor function. However, pregnancy complications were more common in the fetal surgery group, including higher risk of preterm delivery and uterine dehiscence at delivery.[60]

Postnatal assessment

LOCAL EXAMINATION

The sites affected are the lower thoracic, lumbar, sacral, cervical, and upper thoracic regions. In about 80% of infants with myelomeningocele, the defect includes the lumbar region as this is the last part of the neural tube to close. Occasionally, more than one lesion can be found,[59] and there is often concurrent kyphosis or scoliosis. Most myelomeningoceles contain an enlarged subarachnoid space ventrally, with the neural tissue displaced dorsally.

MOTOR FUNCTION

Motor function is assessed when the infant is at rest. Sharp stimulation above the level of the meningocele is administered with careful observation of voluntary movement below the affected level. Varying degrees of paralysis below the level of the lesion are common, except in rarer cervical and upper thoracic lesions, which are usually spared. The paralysis is usually flaccid, indicating a complete neural lesion. It must be borne in mind that there are some abnormal reflex activities in the lower extremities that have no bearing on volitional motor function.

SENSORY LOSS

Sensory loss is determined by pinprick test from distal to proximal, looking for an upper limb or facial response characteristic of those experiencing a pain sensation. The level at which anesthesia starts indicates the myotome level of the lesion and predicts the degree of disability.[61] Fastidious care is necessary to avoid trophic changes in anesthetic areas.

BLADDER AND BOWEL INVOLVEMENT

Over 90% of patients with myelomeningocele have some degree of neurogenic bladder. The vast majority have disturbances of detrusor and sphincter balance resulting in a large, trabeculated bladder with urinary stasis. The external anal sphincter and puborectalis are often involved, resulting in patulous anus and sometimes rectal prolapse. It is difficult to assess bladder involvement in the newborn, but steps should be taken to ensure the bladder is kept empty. There may be associated upper urinary tract abnormalities at birth.[62] All patients need careful urological and renal follow-up.

HYDROCEPHALUS

Eighty-five to ninety-five percent of patients with myelomeningocele have some degree of hydrocephalus. Assessment of the anterior fontanelle and occipitofrontal circumference is important in determining the timing of any CSF diversion procedures. In those infants with clear evidence of hydrocephalus, early CSF diversion is indicated. Delayed placement of a ventriculoperitoneal shunt is not associated with a lower infection rate compared to placement at the time of myelomeningocele closure.[63,64] Almost half of meningocele patients shunted at birth require shunt revision in the first year of life, mostly due to mechanical failure.[65] Endoscopic

third ventriculostomy (ETV) has also been used in some patients, although the failure rate is high when performed as a primary procedure.[66,67] In patients presenting with shunt malfunction, secondary ETV has a better success rate and is therefore best reserved for later management.[66]

CHIARI II MALFORMATION

Chiari II malformation is invariably associated with spina bifida. MRI demonstrates cardinal findings of caudal displacement of the posterior fossa contents, an elongated brainstem, a small fourth ventricle, aqueduct stenosis, and tectal "beaking." Between 25% and 33% of patients are symptomatic from the Chiari II malformation; in the infant, this manifests as brainstem dysfunction associated with sleep apnea and lower cranial nerve palsies. Stevenson et al.[68] reported that apnea, stridor (vocal cord paresis), and swallowing difficulties in infancy were associated with a 15% mortality rate. Whether early decompression improves symptoms remains controversial as surgery-related morbidity and mortality are high in infants (up to 15%–20%).[69,70] From a practical point of view, symptomatic Chiari II is rare in infants as long as the hydrocephalus is correctly managed. Chiari II can become a secondary problem in adult life with delayed deterioration.

SKELETAL ABNORMALITIES

Clubfoot is the most common skeletal abnormality in spina bifida. Other deformities include dislocation of the hip, genu recurvatum, and kyphoscoliosis. Orthopedic assessment and specialist physiotherapy services are required to manage these problems and minimize deformity.

Investigations

A full blood count is obtained, and blood is cross-matched with maternal serum. A plain x-ray of the spine will reveal the extent of the bony abnormality and associated kyphoscoliosis. An ultrasound scan of the head and renal tract are carried out as baseline investigations. MRI of the entire craniospinal axis will determine the presence of associated congenital abnormalities.

Parental discussion

Babies born with NTDs require an ethical and humane approach to management, informed by accurate background information and full involvement of parents in the decision-making process.[15,71] The management of each child should be individualized and reviewed regularly. Despite early closure and deployment of all available therapeutic measures, there is still a significant rate of disability and mortality.[72–74] Lorber[14] previously outlined adverse criteria (including gross paraplegia, severe hydrocephalus, severe kyphosis, thoracolumbar lesions and other associated congenital anomalies; see Figure 96.4), the presence of which might prompt a conservative management strategy. These criteria are based on the belief that these patients will often die early in infancy. These severely affected babies were often managed conservatively with demand feeding and sedation. In an era of improved antenatal diagnosis and prenatal counseling, many of the severe defects are avoided with early termination. Parents are now usually aware of the expected prognosis for intellectual development, ambulation, and survival, after antenatal counseling.

Figure 96.4 Large dorsolumbar myelomeningocele. This baby had bilateral lower limb paralysis, hydrocephalus and bilateral dysplastic kidneys. The baby was managed conservatively.

Operative treatment and technique

All actively treated spina bifida patients should undergo closure of the defect within 24–48 hours of delivery. It was previously thought that early closure resulted in improved neurological outcome,[12] but this has not been supported by more recent studies.[75,76] Early defect closure reduces the risk of infection and further damage to exposed neural tissue—the core aim is to preserve existing function. The principle of surgery is to reconstruct the defect by five-layer closure of the pia and arachnoid, lumbar fascia, subcutaneous tissue, and skin. The vascular supply to the neuroplaque is maintained, and unnecessary neural injury is avoided. The patient is placed in the prone position with a soft roll under the hips and shoulder, and with the head turned to the right through 90° (Figure 96.5a). Swabs are taken from the lesion for microbial examination and culture. An antiseptic soak is placed over the anus. The lesion is covered with a warm swab, and the surrounding skin is cleaned and draped. The skin is incised at the junction of the arachnoid membrane and skin (Figure 96.5b). The membrane between the edge of the skin defect and neural plaque is removed carefully to avoid inclusion of cysts (Figure 96.5c). The dura is freed laterally and then superiorly and inferiorly to normal intact dura (Figure 96.5d). Dura is then sutured in the midline with continuous monofilament absorbable sutures (Figure 96.5e). A suction drain may be placed extradurally, though

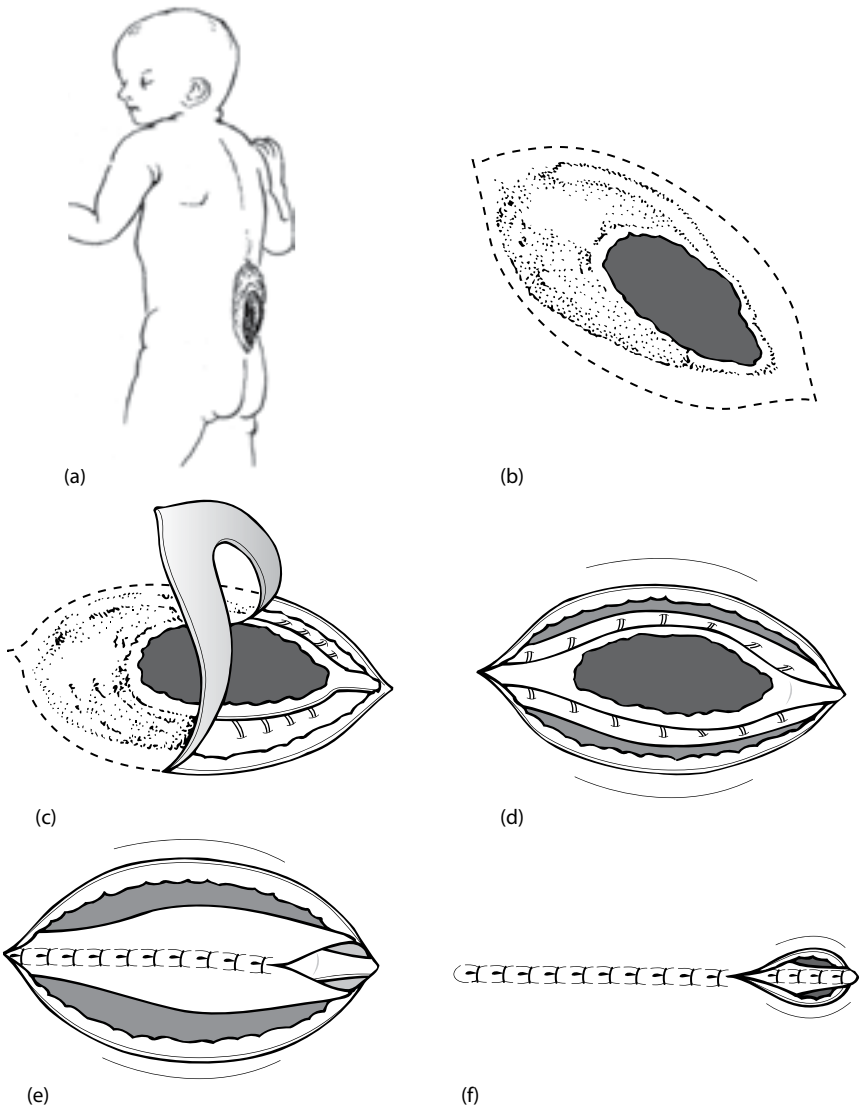

Figure 96.5 Closure of myelomeningocele. **(a)** Position of the patient on the operating table. **(b)** An elliptical incision at the junction of the arachnoid membrane and the skin. **(c)** Membrane is excised and neural plaque freed. **(d)** Dura is dissected laterally from the underlying muscle. **(e)** Dura is closed with an interrupted continuous 5-0 monofilament absorbable sutures. **(f)** Skin is closed with interrupted 5-0 nylon sutures.

this is not mandatory. The lumbodorsal fascia is incised laterally and dissected free from the posterior iliac crest. These are folded medially and sutured over the dorsal dural layer. The subcutaneous tissue is closed with absorbable interrupted sutures, and then the skin is closed with interrupted nylon stitches (Figure 96.5f). The infant is nursed in a prone position. Feeding is commenced once the bowel starts working. The wound is periodically inspected. The suction drain is removed 24–48 hours after operation.

Postoperative management and complications

Infection is common,[77] and treatment is with appropriate antibiotics and local drainage. Wound dehiscence may occur and is usually secondary to undue tension on the skin edges or skin necrosis. If infection is deep to the lumbodorsal fascia, it may cause meningitis or ventriculitis. These are vigorously treated with local dressings, systemic antibiotics, and external ventricular drainage if hydrocephalus or CSF leak occurs. With meticulous closure of the dura, CSF fistula should be rare. However, if it does occur, immediate repair is preferred rather than conservative treatment. Hydrocephalus may be present in about 15% of patients with myelomeningocele at birth, while it eventually develops in 85%. The exact reason for this is not clear; it may be aggravated by a shift in the brainstem after repair, which produces changes in the aqueduct or the Chiari malformation leading to alteration in the CSF flow dynamics. After neurosurgical closure of the defect, and shunt placement if indicated, management is continued in a multidisciplinary team context.

CLINICAL OUTCOME AND LONG-TERM MANAGEMENT

The results of myelomeningocele operations vary considerably because of differences in approach to management. Historically, in the units where a highly selective approach was taken, all conservatively managed patients died, compared with mortality of 14.3% for those actively managed.[78] Contemporary cohort studies illustrate a continuing high mortality rate in adult life. Analyzing a cohort of 117 unselectively closed spina bifida patients over a mean of 40 years showed that 40 died before the age of 5 and a further 31 died in the next 35 years (10 times average mortality).[72]

Medical problems

URINARY INCONTINENCE

Only 10% of myelomeningocele patients have a normal bladder. The remainder have a neurogenic bladder of some degree. The introduction of clean intermittent self-catheterization, pharmacological agents (e.g., anticholinergics), external devices, biofeedback, and innovative surgical procedures has allowed up to 75% of these patients to be socially continent and maintain renal function.[79] Urodynamic studies in the newborn period are useful in identifying at-risk children with high bladder pressure and detrusor instability.[80,81]

CHIARI II MALFORMATION AND HINDBRAIN DYSFUNCTION

Older children and young adults with Chiari II malformation may complain of symptoms related to foramen magnum impaction such as headache, neck pain, and upper limb sensory disturbance. Brainstem dysfunction and lower cranial nerve palsies may also be present. Surgical treatment may be indicated in symptomatic patients, once adequate CSF diversion by either shunting or ETV has been established.[82] In our own series of 21 patients with myelomeningocele surviving into adulthood, 8 patients underwent foramen magnum decompression for late deterioration, with consequent stabilization of symptoms.[83]

HYDROCEPHALUS

Shunt placement has a significant impact on the future life of the child and parents. In myelomeningocele patients, shunt malfunction and complications (e.g., infection, hemorrhage) impair cognition[84] and impact long-term survival.[73,85,86] If shunt malfunction occurs in later childhood, then ETV has a 89% success rate and should be considered before shunt revision.[82]

Lifestyle issues

Whether patients are managed conservatively or actively, quality of life is an important factor in those who survive. In the long-term follow-up study by Oakshott and Hunt,[72,73] of 117 patients treated unselectively who were followed up for 16–20 years, it was found that 41% died before 16 years of age. Of the survivors, almost 31% were mentally disabled, 48% were unable to live without help or supervision, and only about one-quarter of survivors were capable of competitive employment.[72,73]

INTELLIGENCE

Patients who have associated hydrocephalus and episodes of shunt malfunction (blockage and infection) have lower intelligence than those who only have myelomeningocele.[84] In addition, cognitive impairment can be consequent to associated structural defects, rather than repeated episodes of hydrocephalus.[87,88] Fiber tract anomalies in the limbic system have been correlated with memory deficits.[87] In a small adult cohort undergoing in-depth neuropsychological testing at our own center, visuospatial construction and memory were impaired in all myelomeningocele patients.[83] Importantly, severely physically disabled patients who have relatively mild cognitive impairment may yet be self-supporting and in competitive employment.

AMBULATION

Ambulatory potential and capacity are related to intelligence, orthopedic deformity, level of lesion, obesity, and motivation. Most of the patients with lesions below L5 are ambulators, those with lesions at L4 are functional ambulators, and those with lesions above L3 are wheelchair-bound.[89,90] The proportion of those patients who retain ambulant status into adulthood gradually decreases due to combinatorial factors including increasing weight, spinal and foot deformity, and respiratory compromise. Long-term follow-up studies have reported that only 30% of patients remain ambulant at 30 years of age.[91] A wheelchair may become a more energy-efficient means of mobility.[92]

PSYCHOSOCIAL PROBLEMS

Educational mainstreaming, special counseling, improved understanding of the patient's potential, and increased public awareness of spina bifida all contribute to a reduction in stress to patients and parents.

ENCEPHALOCELE

Encephalocele constitutes 10%–20% of all NTDs and has a prevalence of between 1 in 2000 and 1 in 5000 live births.[1,93] Encephaloceles have a higher incidence in Asian countries compared with the West.

Pathology

Encephalocele is a defect in the cranial vault, which is either oval or circular and of variable extent, ranging from a skin-covered meningocele to gross herniation of abnormal brain. These abnormalities are classified according to location as occipital, parietal, frontal, nasopharyngeal, nasal,

frontoethmoid, or basal. Occipital encephalocele is the most common type in the western world, while a frontal lesion predominates in Asia.[59] The contents of the encephalocele vary according to its location and size. Brain tissue is found in 25–80% of cases, usually in occipital encephalocele. In addition to the brain tissue in the sac, the rest of the brain (especially the optic pathway) is distorted, and there may be associated microgyria, holoprosencephaly, heterotopia, agenesis, hydrocephalus, cerebellar aplasia, pyramidal tract aplasia (causing spasticity), and spinal cord distortion. Encephaloceles are commonly associated with other congenital anomalies including spina bifida, Klippel–Feil syndrome, facial cleft, and renal, cardiac, and pulmonary anomalies.

Clinical features

Most encephaloceles are obvious at birth, and some are diagnosed prenatally. The size, content, and location are variable (Figure 96.6), and there may be an overlying hamartomatous lesion. A pulsatile mass that increases in size with crying is the classical sign of an encephalocele. Anterior lesions may cause airway obstruction. Occasionally, the diagnosis may be delayed and only becomes evident when CSF leak occurs and the child presents with recurrent meningitis. A full neurological examination is necessary to determine whether any spasticity, focal motor weakness, or visual impairment exists. Physical examination will reveal any associated anomalies.

Differential diagnosis

The anterior lesion can be difficult to diagnose and may need to be differentiated from a nasal polyp, glioma, dermoid cyst, teratoma, neurofibroma, meningioma, and hamartoma.

Figure 96.6 Occipital encephalocele.

Figure 96.7 Encephalocele. Sagittal T1-weighted MRI shows a large mass arising from the occipital region.

Investigations

Craniospinal MRI should be performed on all patients with encephalocele to determine the severity and extent of the abnormality, as well as screening for associated congenital malformations (Figure 96.7). Visual evoked response will establish the presence of the occipital cortex within the sac, which may be helpful in surgical planning.

Treatment

Conservative treatment may be justified for patients with microcephaly and large amounts of brain within the encephalocele, where death is inevitable. Most patients are treated by surgical repair of the encephalocele. The aims of surgery are excision of extracranial nonfunctioning brain tissue, closure of the dura at the level of the cranium, and restoration of cranial contour with good skin coverage. Taking these steps helps to prevent infection and preserve function.

OPERATIVE TREATMENT AND TECHNIQUE

Under general anesthesia, the patient is positioned with the encephalocele uppermost. The lesion is prepped and draped while ensuring adequate support for the encephalocele. Large lesions may be aspirated to facilitate handling and dissection. A sample of CSF is sent for microbiological examination and culture. Usually, a transverse ellipse incision is made near the base of the lesion, planned to enable wound closure without tension (Figure 96.8). The incision is then deepened until the dura is seen, which is traced up to the bony defect.

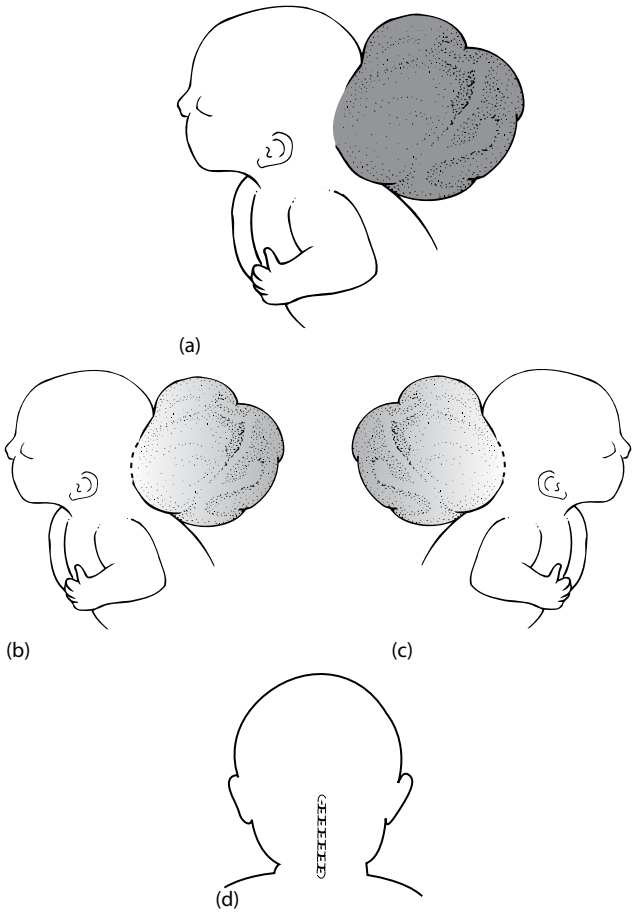

Figure 96.8 Closure of encephalocele. **(a)** Diagrammatic representation of occipital encephalocele. **(b** and **c)** Incision around the base of the encephalocele. **(d)** Skin closure.

The sac is opened where the cerebral tissue is not adherent. If the cerebral tissue is too large, or necrotic, or if no visual evoked potentials are demonstrated, it is excised. Every effort should be made to preserve brain tissue without causing an acute rise in intracranial pressure. Bony defects may sometimes need to be enlarged. While dissecting the dura and brain tissue, particular care must be taken to avoid abnormal venous sinuses and venous connections. The distal sac is then excised. The dura is closed with continuous monofilament absorbable sutures, and a dural graft may be required (pericranium is ideal). Meticulous hemostasis is achieved with the closure of all layers. A small suction drain is occasionally used. Subcutaneous tissue is approximated with fine, absorbable interrupted sutures, and the skin is closed with interrupted nylon or continuous absorbable subcuticular stitches (Figure 96.3). A dressing and bandage is applied.

POSTOPERATIVE CARE AND COMPLICATION

The infant is nursed opposite to the surgical site to minimize pressure on the wound He or she is closely observed for signs of increasing intracranial pressure or development of hydrocephalus. Meningitis is common with anterior encephalocele repair, where contamination is more likely because of proximity to the nose, mouth, and air sinuses. An intracranial approach may help to avoid this. CSF leak can occur despite meticulous dural closure. Once hydrocephalus has been excluded with a CT scan, CSF leaks are managed with additional skin sutures and a lumbar drain. If CSF leak persists, revisional surgery may be required. Most infants with encephalocele repair develop hydrocephalus requiring a CSF shunt.

RESULTS

Encephalocele carries a high rate of mortality (up to 50%).[36] These deaths may be due to cerebral anomalies, other associated congenital abnormalities, an acute rise in intracranial pressure, or complications related to management of hydrocephalus.

PROGNOSIS

Simple isolated encephalocele without associated abnormalities has a better prognosis. Larger lesions, those associated with microcephaly and hydrocephalus, and those forming part of other syndromes (e.g., trisomy 18, Meckel syndrome) have a poorer prognosis.[94,95] Anterior encephalocele has a poorer prognosis than posterior encephalocele.

Hydrocephalus

JOTHY KANDASAMY, MAGGIE K. LEE, MARK A. HUGHES, AND CONOR L. MALLUCCI

INTRODUCTION

The term *hydrocephalus* relates to the presence of an excessive amount of cerebrospinal fluid (CSF), which may cause an increase in intracranial pressure with or without abnormal enlargement of the cerebral ventricles. Hydrocephalus can result from a variety of pathological processes or insults that cause imbalance between production and absorption of CSF. Numerous classifications and categories exist with two widely used and pragmatically helpful subdivisions: obstructive (where there is macroscopic obstruction to bulk flow of CSF within the ventricles) and communicating hydrocephalus (where there is inadequate absorption of CSF from the subarachnoid space).

The estimated prevalence of congenital and infantile hydrocephalus is between 0.5 and 0.8 per 1000 births (live and still).[1–3] Until the advent of viable shunts (over 60 years ago), hydrocephalus was usually fatal. The mainstay of treatment of hydrocephalus in the infant remains CSF diversion with shunting. However, neuroendoscopic procedures (predominantly endoscopic third ventriculostomy [ETV]) are increasingly utilized in certain situations. Technological advances in neuroimaging, neuronavigation, and shunt hardware, and a better understanding of CSF dynamics is leading to a more patient-specific approach to this complex and multifactorial problem. Hydrocephalus may cause pathological changes to brain morphology, microstructure, circulation, biochemistry, metabolism, and maturation. Although treatment does not always reverse the damage, the timing of therapy is crucial in determining reversibility and outcome for the patient.

CSF CIRCULATION

The three components influencing CSF dynamics are production, circulation, and drainage. CSF is derived by adenosine triphosphate (ATP)-dependent active secretion from cerebral arterial blood across epithelial walls. The global average rate of CSF production is constant under normal and stable conditions at 0.35 mL per minute.[4,5] The current widely accepted view is that CSF circulation is via bulk flow.[6] Produced mainly in the choroid plexus of the lateral and third ventricles, CSF flows along the aqueduct of Sylvius to reach the fourth ventricle. CSF flows out of the fourth ventricle through the midline foramen of Magendie and the lateral foramina of Luschka into the subarachnoid space, comprising an interconnecting network of basal CSF cisterns. Most CSF flows around the convexities of the brain upward to the superior sagittal sinus. Some CSF flows downward toward the lumbar subarachnoid space. CSF drains into the venous compartment, predominantly via a pressure-dependent one-way pathway through arachnoid granulations in the walls of the superior sagittal sinus.[4,6]

Although our understanding of CSF dynamics is incomplete, the distinction between communicating and obstructive hydrocephalus is important (albeit sometimes knowingly inaccurate) as it informs treatment options. Obstruction of CSF flow between the third and fourth ventricles results in accumulation of CSF in the lateral and third ventricles. This may be the result of a congenital or acquired stenosis of the aqueduct, or due to a compressive mass in the posterior fossa. Endoscopic fenestration of the floor of the third ventricle (creating a new pathway for CSF to enter the subarachnoid space) can be effective in this situation. Meningitis or hemorrhage in the subarachnoid space can both impair CSF flow and also impede absorption through arachnoid granulations. In this context, third ventriculostomy is less likely to be effective, and shunting may be necessary.

CAUSES OF HYDROCEPHALUS

The numerous causes of hydrocephalus are out with the scope of this chapter. Only those most relevant to the newborn are outlined and divided into the following causative categories: obstructive hydrocephalus (radiologically visible obstructive lesion), communicating hydrocephalus

(no radiologically visible obstructive lesion), external hydrocephalus, and rarely, overproduction of CSF.

Obstructive hydrocephalus

AQUEDUCT STENOSIS

This accounts for 6%–66% of cases of hydrocephalus in children. In the vast majority of cases, aqueduct stenosis is sporadic or acquired. However, rare X-linked syndromic cases have been described.[7] Aqueduct obstruction may be caused by gliosis secondary to infection or hemorrhage, or due to compression from neoplastic (e.g., tectal tumors), vascular (e.g., vein of Galen aneurysms), or congenital central nervous system (CNS) malformations (Dandy–Walker, Chiari, Spina Bifida). Magnetic resonance imaging MRI is mandatory to assess the patency of the aqueduct, which cannot be visualized adequately on computed tomography (CT).

SPINA BIFIDA AND CHIARI MALFORMATION

Approximately 95% of patients with spinal myelomeningocele have some degree of hydrocephalus, which is almost invariably associated with the Chiari II malformation.[8] The major craniocervical features of a Chiari II lesion include the following: caudal displacement of the fourth ventricle into the upper cervical canal, elongation and thinning of the upper medulla and lower pons, caudal displacement of the medulla and lower cerebellum through the foramen magnum, and various bony defects of the upper cervical vertebrae and occiput.[9] Please refer to Chapter 96, "Spina Bifida and Encephalocele."

Dandy–Walker complex and posterior fossa cysts

The *Dandy–Walker complex* refers to a rare group of malformations in which abnormal posterior fossa CSF collections show clear communication with the fourth ventricle. Dandy–Walker malformation is included in this category and typically involves cystic dilatation of the fourth ventricle, partial or complete agenesis of the cerebellar vermis, and hydrocephalus in up to 90% of cases.[10] It can be associated with other nervous or systemic abnormalities. Posterior fossa arachnoid cysts do not communicate directly with the fourth ventricle. Both third ventriculostomy and shunting are valid surgical options, and overall morbidity appears to be related to early and adequate treatment of the associated hydrocephalus.[11,12]

NEOPLASTIC LESIONS

Fortunately, brain tumors in newborns are very rare. The most common types are often of neuroectodermal origin and are more commonly supratentorial. Any neoplastic lesion can cause hydrocephalus due to obstruction of CSF pathways.

Communicating (nonobstructive) hydrocephalus

POSTHEMORRHAGIC HYDROCEPHALUS

Hemorrhage in the neonatal period is a common cause of hydrocephalus.[13,14] The premature infant born before gestation week 32 is especially vulnerable. Hemorrhage most commonly originates in the highly vascularized germinal matrix. Most studies agree that the incidence is highest in infants weighing less than 1.5 kg at birth, and up to 50% of hemorrhages occur within 8 hours of birth.[13,14] In the term neonate, the most common site of hemorrhage is the choroid plexus, but this accounts for only a small percentage of neonatal hemorrhages. Posthemorrhagic hydrocephalus (PHH) can be defined as progressive dilation of the ventricular system as a complication of neonatal intraventricular hemorrhage (IVH). Hemorrhage is postulated to provoke an inflammatory response leading to thickening of the arachnoid in the basal cisterns and temporary or permanent occlusion of the arachnoid villi.[15] PHH may contain elements of both communicating and obstructive hydrocephalus, at varying stages. The incidence of PHH after IVH of prematurity ranges from 25% to 74% and is proportionately linked to the blood load within the ventricular system.[14] The continuous improvement in perinatal care has led to increased survival rate of preterm infants and thus a greater risk of these infants developing IVH and PHH. Fernall et al. reported that an infant born very preterm has a 60 times higher risk of developing infantile hydrocephalus than an infant born at term.[16] Ultrasonography is sensitive and specific in diagnosing IVH, and some advocate routine ultrasonography in any infant born before 34 weeks' gestation and/or for those infants weighing less than 1.5 kg at birth.[17–19] Most IVHs are small and resolve spontaneously. More severe hemorrhages are associated with an increased risk of developing PHH and higher risk of mortality and neurodevelopmental impairment.

The risk of IVH in the preterm infant has been reduced significantly by measures that indirectly ameliorate fluctuation in cerebral blood flow (such as surfactant to reduce pulmonary hypertension and antenatal steroid administration).[16,20] Some advocate that premature infants should be maintained on paralytics and sedated for the first 72 hours following birth to reduce the risk of IVH.[20] Once PHH has been diagnosed, temporizing interventions can be employed. Ventricular access devices (VADs), external ventricular drains (EVDs), ventriculosubgaleal (VSG) shunts, or lumbar punctures (LPs) are potential temporizing strategies. VSG shunts may reduce the need for daily CSF aspiration compared with VADs. The routine use of serial LP is no longer recommended as a means of reducing the downstream need for a shunt.[21] Some patients are too unstable for surgery, or their hydrocephalus may resolve after degradation of the IVH. Most cases of PHH occur 3–4 weeks after IVH. Importantly, many cases are clinically silent, and early detection requires a high index of suspicion and

serial radiological monitoring. Of those that develop PHH, over 50% become shunt dependent, with a high rate of neurodevelopmental disability. Medical and surgical management options will be discussed in the next sections of this chapter.

POSTINFECTIVE HYDROCEPHALUS

Intrauterine infection by cytomegalic inclusion disease, mumps, toxoplasmosis, and syphilis can cause congenital hydrocephalus. Postnatal meningitis and or ventriculitis can also lead to hydrocephalus from obstruction to arachnoid granulations and/or obstruction to CSF flow in the basal cisterns. Meningitis in the newborn may result from amniotic infection where the membranes have been ruptured for a prolonged period. In the first 2 weeks of life, the organism is usually *Escherichia coli* or other Gram-negative enteric bacilli. In the second 2-week period, Gram-positive cocci, *Listeria*, and *Pseudomonas* are more common.[22–24] Postinfective hydrocephalus (PIH) typically occurs 2–3 weeks after diagnosis of bacterial meningitis. Associated complications include abscess formation, ventriculitis and subsequent CSF loculations and intraventricular septations.[24,25] The management is difficult and frequently requires multiple shunts and revisions, with consequent poor development and high morbidity and mortality.

External hydrocephalus

This controversial entity is also linked to or referred to as *pseudohydrocephalus*, *benign subdural effusion*, *benign enlargement of the subarachnoid spaces*, and *benign pericerebral effusion*. Its etiology and pathophysiology are uncertain, but they describe abnormal collections of fluid in the subarachnoid or subdural space overlying the cerebral convexity. The condition occurs while the cranial sutures are open. Most cases do not require intervention and follow a benign course. Rarely, a subdural-peritoneal shunt is required if a patient presents with features related to mass effect and raised intracranial pressure.

Overproduction of CSF

Choroid plexus papillomas are intraventricular tumors that cause overproduction of CSF and resultant ventricular enlargement. They are most often found in the lateral ventricle and appear as homogenously enhancing lesions on MRI. Resection of the tumor may be curative if the tumor is benign.

CLINICAL FEATURES OF HYDROCEPHALUS IN THE NEWBORN

Despite a vast variation in underlying etiology, clinical presentation of hydrocephalus is remarkably consistent and relates to signs and symptoms of localized or generalized raised intracranial pressure.

An increase in head size is the major feature of hydrocephalus in the neonate, with increasing deviation of head circumference from the normal centiles for age. Incremental plotting of head circumference is essential in this regard, using a centile chart such as that produced by Gairdner and Pearson, which corrects for gestational age at birth.[26] It should be noted that there are causes for head enlargement other than hydrocephalus (e.g., a familial tendency for a large head, osteofibromatosis, macrocephaly or intracranial cysts). The head *shape* may also be abnormal.

Bulging of the anterior fontanelle with a variably open posterior fontanelle, separation of the suture lines, and dilatation of superficial scalp veins (due to venous reflux from cerebral sinuses) are classical features of raised intracranial pressure in hydrocephalus. "Setting sun sign," an upward gaze palsy, may be seen. This phenomenon consists of downward rotation of the eyeballs and retraction of the upper eyelids and may be accompanied by brow raising. Sixth-nerve palsy can occur due its sensitivity to pressure during its long intracranial course. Papilledema, decreased level of consciousness, and other focal neurological deficits can also be presenting signs. Opisthotonic posturing and bradycardic and apneic episodes are critical signs of raised intracranial pressure suggesting brain-stem compromise. This demands emergent neurosurgical assessment and treatment.

Other important, though less specific, presenting symptoms of hydrocephalus in the infant include irritability, lethargy, poor feeding, vomiting, failure to thrive, and delayed motor development. Clinical presentation may also include features specific to the underlying causative pathology.

CURRENT IMAGING AND INVESTIGATIVE TECHNIQUES FOR HYDROCEPHALUS IN THE NEWBORN

Skull x-rays are largely obsolete in the management of hydrocephalus in the newborn. Historically, widening of the sutures beyond 3 mm, with associated *lacunar* skull defects, was suggestive. Ultrasonography is exceptionally useful as a noninvasive technique (Figure 97.1).[17–19] Antenatal sonography can detect hydrocephalus in utero and is the screening procedure of choice in patients under the age of 18 months. In the newborn, the anterior fontanelle provides a window. Measurements of both the ventricle size and the cortical mantle are possible. Serial ultrasonography has not only improved the ability to detect hydrocephalus but also resulted in more prompt treatment. Ultrasound has proven especially useful in detecting IVH and associated hydrocephalus in premature infants. It is considered the initial investigation of choice for neonates with hydrocephalus (Figure 97.1) and can be performed at the bedside.[17–19] Although sensitive and specific for the detection of hydrocephalus, clarification of underlying cause usually necessitates CT or MRI.

Figure 97.1 Aqueduct stenosis. Coronal section on sonography showing dilated lateral ventricles and foramina of Monro passing into a dilated third ventricle.

A complete high-resolution CT can be obtained within 2 minutes of the patient being on the CT table (Figure 97.2). MRI is the gold standard for diagnosing the *cause* of hydrocephalus and demonstrates the ventricular and CSF anatomy in exquisite detail. Pathological entities such as aqueductal stenosis, Chiari malformation, and neoplastic lesions are readily identifiable. MRI also allows detailed surgical planning when considering ETV, shunting, posterior fossa surgery, and so forth. MRI dynamic flow sequences can highlight relevant ventricular, periventricular, and other CSF flow with remarkable clarity.[27] This is particularly useful when assessing the anatomy of the third ventricle and aqueduct. Volume data sets (for both CT and MRI) allow bespoke intraoperative three-dimensional neuronavigation for shunting and neuroendoscopic procedures. MRI is increasingly used as an antenatal investigation and is valuable in both characterizing congenital malformations and detecting hemorrhage.[28]

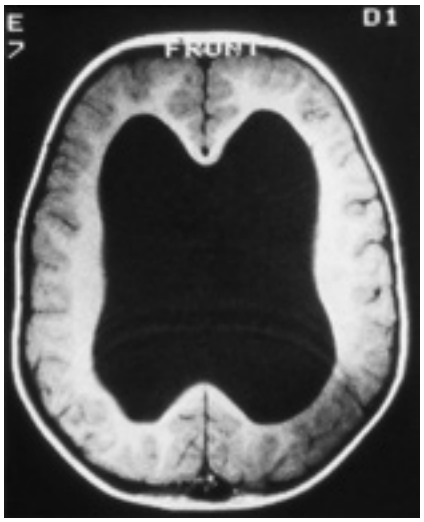

Figure 97.2 CT scan of head showing dilated lateral ventricles.

Postoperative imaging to assess ventricular size after shunting or neuroendoscopy can be performed with both CT and MRI. However, after a third ventriculostomy, phase contrast dynamic MRI sequences are required to identify CSF flow through the new stoma.[27,29] Invasive pressure measurements such as fontonometry are less often justified as they are unreliable compared with modern methods of imaging.

An antibody screen should be carried out if an intrauterine infection is suspected. CSF analysis is indicated where infection or hemorrhage is suspected. A raised protein level, or indeed bloodstained CSF, is not necessarily a contraindication to shunting but may inform the timing of shunt placement. It may be appropriate to delay surgery until the protein count and/or the blood in the CSF clears. If active infection is suspected, a temporizing EVD is preferable. Once the infection is fully treated and the CSF is sterile, a permanent shunt can be implanted.

TREATMENT OPTIONS FOR HYDROCEPHALUS IN THE NEWBORN

Nonsurgical/medical management

The complications associated with surgery in the low-birthweight neonate, or neonates with unstable comorbidities, demand that nonsurgical means of managing hydrocephalus be considered. However, pharmacotherapeutic agents such as acetozolamide, frusemide, and steroids have not been shown to be effective in reducing the rate of shunting and are not recommended.[30,31] Although historically common practice, serial LPs are no longer recommended. Meta-analysis found no evidence of benefit but a significant risk of secondary infection.[21,32] Similarly, serial percutaneous ventricular taps have been abandoned by most tertiary neurosurgical centers due to frequent complications such *puncture porencephaly*, infection, and encephalomalacia.[33,34]

Surgical management

Surgery remains the overwhelming mainstay of treatment for hydrocephalus in the newborn. Shunting converted hydrocephalus from what was almost universally fatal to a treatable condition. The first permanent CSF diversion for hydrocephalus was performed by Mikulicz in 1893 in the form of a ventriculo–subarachnoid–subgaleal shunt.[35] Since then, virtually every anatomical cavity has been trialed as a potential reservoir or conduit for CSF drainage. This section outlines the most common surgical techniques in newborn hydrocephalus surgery.

EXTERNAL VENTRICULAR DRAINAGE

EVD is used widely in the temporary treatment of hydrocephalus. The frontal and occipital horns of the lateral ventricles are the target site, accessed via a single burr hole. CSF is drained at the desired rate into a sterile closed-circuit

system. EVD is of use in the presence of active infection (where a permanent shunt system would become colonized) or when time is required to allow a transiently high CSF pressure to normalize. EVDs also provide a route for administration of intrathecal antibiotics into the infected CSF space. Similarly, EVD is useful in IVH or PHH as a temporizing measure before either persistent hydrocephalus declares itself or the blood load has reduced. In an emergent setting arising from tumor-related obstructive hydrocephalus, EVD allows decompression of the ventricular system prior to more planned definitive tumor resection. Despite the introduction of antibiotic-impregnated EVDs, these are still prone to significant infection rates, and catheters are also easily dislodged. Several studies have assessed the efficacy of intraventricular fibrinolytic therapies and CSF irrigation. With the advent of improved neuroendoscopic equipment and approaches, these techniques continue to be considered as there is some evidence that long-term outcomes may be improved in neonates with IVH-related hydrocephalus.[21,34,36,37]

SUBCUTANEOUS VAD

Here, the ventricular catheter connects to a subcutaneous reservoir under the scalp. This device may be indicated in the newborn infant whose low birth weight and/or the potential for spontaneous arrest of hydrocephalus preclude the immediate need for a permanent shunt. It is a viable option in PHH. The reservoir allows easy CSF tapping, lower infection rates compared to EVD, and access for intraventricular antibiotics. Complications and limitations include skin erosion, CSF leak, and only intermittent pressure control.

VENTRICULOPERITONEAL SHUNT

The majority of hydrocephalic newborns undergoing CSF diversion surgery will have a ventriculoperitoneal shunt (VPS). The principle of VPS remains unchanged since first described in 1908.[35] Initially, ventriculoatrial (VA), or ventriculopleural (VP) shunts were considered preferable. The peritoneum became the drainage site of choice as complications with VA shunts, such as sudden death from pulmonary embolism, endocarditis, and nephritis, were noted. Another problem in VA shunts in the neonate is the need to lengthen the lower end as the child grows and the catheter pulls up out of the atrium. This can be obviated with VPS by placing a long intraperitoneal catheter allowing scope for growth. The hardware required for a VPS includes a ventricular catheter, CSF reservoir, shunt valve, and distal peritoneal catheter. Recently, antibiotic-impregnated and antibiotic-resistant shunt tubing have been gaining popularity. Their capacity to reduce infection is currently under investigation via a large multicenter randomized controlled trial (RCT) (British Antibiotic and Silver Impregnated Catheters for VPS, http://www.basicsstudy.org.uk/index.html).[38]

The choice of shunt valve also remains a regular source of debate within the neurosurgical community. Valve types include differential pressure, flow regulating, gravity-actuated, and programmable. All valves only allow unidirectional flow of the CSF. An antisiphon device may be included in the system to prevent positional over-drainage. There are no studies that conclusively prove one valve type to be superior to another.[39–41] In practice, some factors that may influence choice include valve size/profile, cortical mantle thickness, cost, and individual surgeon experience. Some authors advocate a flow control valve for shunts in the newborn to avoid the downstream complication of slit ventricle syndrome. This is related to chronic overdrainage and seen most commonly in patients who have a shunt implanted in the first 2 years of life.[42] Overdrainage and development of subdural hematomas in newborns with large ventricles and thin cortical mantle may be avoided with high-resistance valves.[43]

Some advocate the use of a VPS in combination with a separate VAD. A VAD allows easy sampling of CSF for microbiological assessment, is a means of assessing CSF pressure, and is an easy access point for external drainage in the event of shunt blockage. Arguably, this can reduce unnecessary shunt explorations. The additional procedure of VAD insertion is not associated with increased patient morbidity.[44]

Both frameless and frame-based neuronavigation systems have been utilized to optimize the position of ventricular catheters. Recent studies have shown benefit in catheter placement accuracy, but it remains uncertain whether this translates into lower shunt revision rates in the long term.[45] With the electromagnetic (EM) frameless neuronavigation systems, there is no requirement for rigid head fixation with pins or screws. This confers a significant advantage for neonatal shunt surgery. Previous studies on endoscopic versus nonendoscopic catheter placement did not demonstrate any difference in shunt revision rates.[46]

Common complications of VPS include infection, malposition of the ventricular catheter, mechanical failure leading to blockage, overdrainage, and shunt migration. Less common complications include bowel perforation, hernia, hydrocele, appendicitis, and peritonitis. Shunt complication rates are significantly higher in the newborn, and studies have shown low birth weight to be linked to a higher incidence of shunt infection and revision rates.[47] If the CSF is sterile on insertion, the most common organisms responsible for postoperative infection are skin commensals such as *Staphylococcus epidermidis (albus)*. Where infection is proven, removal of the entire shunt system, temporary CSF diversion via an EVD, and concomitant intrathecal antibiotic administration are usually necessary. The treatment of shunt infections has been reviewed extensively by Bayston et al.[48]

Despite advances in neuronavigation and shunt hardware, shunt failure remains a considerable source of morbidity for those with hydrocephalus. Up to 40% of shunts fail in the first year.[49] Indeed, shunt failure is an almost inevitable consequence during a patient's life, with up to 80% of shunts requiring revision within 12 years.[50]

NEUROENDOSCOPY AND ETV

Advances in fiber-optic camera technology, combined with high-resolution MRI, have renewed enthusiasm for neuroendoscopy as a therapeutic option in hydrocephalus. ETV was first performed as an open procedure by Dandy in 1922 and subsequently as an endoscopic procedure by Mixter in 1923.[34]

ETV is a minimally invasive procedure. A single paramedian coronal burr hole allows access into the lateral ventricle. The ventricle is entered with a 10- or 12-French cannula, which serves as a conduit for the rigid or flexible endoscope. The endoscope is advanced toward and into the enlarged foramen of Monro and then into the third ventricle. A midline fenestration is formed, and dilated, in the thinned floor of the third ventricle—avoiding critical structures such as the mammillary bodies and the basilar artery. The endoscope is then advanced through the fenestration to ensure that an effective communication into the interpeduncular and prepontine subarachnoid space has been achieved. At completion, the endoscope and cannula are removed, and no hardware is left in situ.

Circumventing the need for a shunt is an attractive surgical option. However, current evidence suggests that patient selection is crucial to success.[51] ETV in obstructive hydrocephalus with maintained CSF absorption (such as in congenital aqueduct stenosis) is associated with the highest success rates. While in older children, the indications for endoscopic treatment have been relatively well defined, debate continues on the utility of ETV in the first few months of life.[52–54] Various studies have reported differing success rates, and there remains a lack of consensus in infants and neonates.[55]

The International Infant Hydrocephalus Study (IIHS) is an international multicenter prospective SCT of ETV versus shunting in children presenting under the age of 2 years with pure aqueduct stenosis.[56,57] The role of ETV as a secondary treatment option after initial or multiple shunt failures is gaining popularity.[58] This is relevant to the newborn with PHH or PIH who may benefit from a primary shunt (where primary ETV is ineffective) and can then be considered for a secondary ETV when presenting with a future shunt failure.

ETV may also have an important role in treatment of hydrocephalus in less economically developed countries.[59] The paucity of a follow-up in this context reinforces the advantage of a shunt-free option. PIH accounts for up to 60% of hydrocephalus cases in some developing countries.[59] In a relatively large series of patients treated in one developing country, success rates were lower in the under-1-year group compared with older children (mirroring findings in more economically developed regions). Nevertheless, ETV has enabled up to 60% shunt avoidance in developing-country infants with PIH causing acquired aqueduct stenosis.[59] The combination of ETV and choroid plexus cauterization (CPC) may also be a viable option in temporarily reducing CSF production until absorptive capacity improves. A study employing this technique in the developing world reported a success rate of over 70% in infants under 1 year old with PIH and an open aqueduct.[60]

Other applications of neuroendoscopy include aqueductal stenting (for isolated fourth-ventricle enlargement), septum pellucidotomies (for multiloculated hydrocephalus), cyst fenestration, and as an adjunct to shunt surgery by aiding shunt placement under direct endoscopic vision.

Although safe in well-trained and experienced hands, complications of neuroendoscopy can be devastating. Severe hemorrhage, cardiac arrest, cerebral infarction, diabetes insipidus, and damage to the fornices (resulting in memory deficit) have all been reported.[61] Also important is the rare but potential risk of sudden post-ETV death due to closure of the ventriculostomy.[61] Nevertheless, neuroendoscopy—together with advances in computerized neuronavigation—has an increasingly important role in the management of hydrocephalus.

FETAL SURGICAL THERAPY

Hydrocephalus is detectable in utero, raising the question of prenatal intervention. In spite of extensive experimental work, and indeed some human intervention in countries where abortions are legally banned, results on the whole have been poor.[62] The majority of patients who have undergone fetal surgery for hydrocephalus required VPS insertion after birth.

However, fetal surgery in the context of myelomeningocele, has been shown to reduce the rate of subsequent shunting. The Management of Myelomeningocele Study (MOMS) was a multicenter randomized prospective trial comparing prenatal (18–25 weeks of gestation) and postnatal repair of myelomeningocele. Outcomes assessed include death, the need for ventricular shunting by 1 year of life, and neurological function at 30 months of age. MOMS found that prenatal surgery for myelomeningocele reduced the rate of shunting (40% compared with 82%) and improved a composite score of mental development and motor function. However, pregnancy complications were more common in the fetal surgery group, including higher risk of preterm delivery and uterine dehiscence at delivery.[63]

Shunt operation technique

VENTRICULOPERITONEAL SHUNTS

The patient is positioned while under general endotracheal anesthesia. Antibiotic prophylaxis at induction is recommended. The head is turned to the opposite side of intended shunt placement, with the neck extended slightly to create a straight line between the scalp and abdominal incision. The site of the burr hole and abdominal incision is to be marked prior to skin preparation and draping (Figure 97.3), Occipital burr holes are usually 3–4 cm from the midline along the lambdoid suture. Frontal burr holes are 2–3 cm along the coronal suture from the midline. It is vital to tailor the burr hole to the ventricular morphology, so as to ensure optimal ventricular catheter placement. In infants with

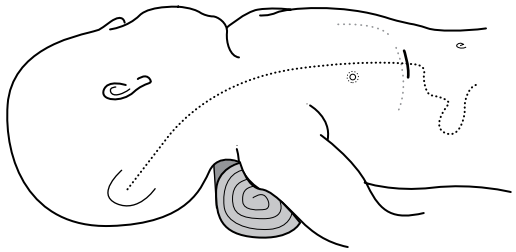

Figure 97.3 The dotted line represents the course of the ventricular catheter. The patient is positioned with a roll of Gamgee under the shoulders to straighten out the neck and allow easier passage of the cannula. The skin is marked, predisinfection, with a pen, showing the curved incision site behind the posterior parietal eminence. The transverse abdominal incision site is also marked with a dark line.

splayed sutures, access can be achieved via an opening of the sutures. The site of a burr hole is of surgeon's preference; there is little evidence showing advantages of one over the other. Occipital burr holes are more cosmetically acceptable (Figure 97.4a). After the burr hole, a durotomy is performed, and the brain pia is cauterized. Dural opening should be kept minimal to reduce the risk of CSF egress around the ventricular catheter (increasing risk of CSF leak from the wound) (Figure 97.4b).

The abdominal incision is usually performed on the same side in either an upper midline or paraumbilical site. The most important step is ensuring that the peritoneum is opened. Open technique, use of a trocar,[64] or using laparoscopic assistance have all been described.[65] The distal catheter is tunneled subcutaneously from the burr hole site to

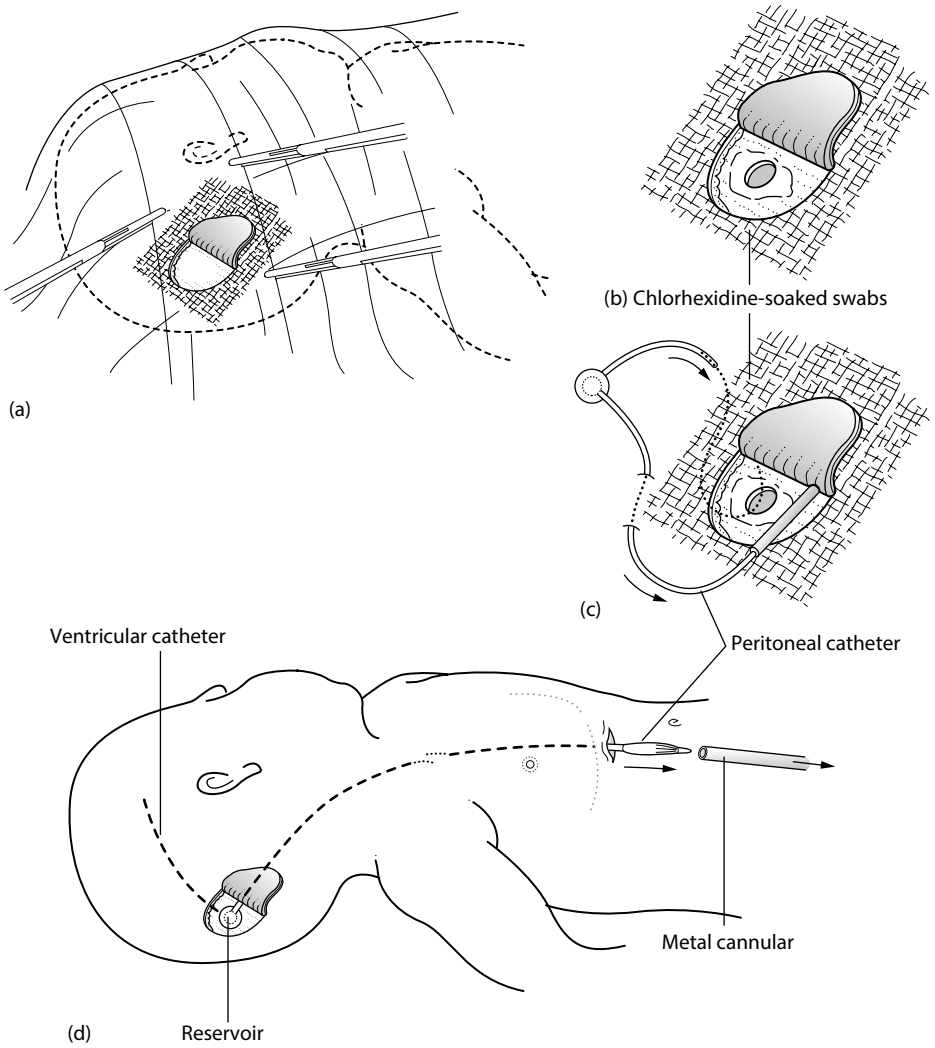

Figure 97.4 **(a)** Wound drapes surrounding the scalp incision. Upper incision to pericranium is made. **(b)** The pericranium is diathermied and rasped peripherally and a burr hole made. **(c)** Following incision in the abdomen, a long trocar and cannula are passed percutaneously to exit at the lower incision. The long trocar is removed, allowing passage of the peritoneal catheter along the metal cannula. The trocars in some prepared shunt sets have a device for attaching the distal catheter and allowing it to be pulled through distally. **(d)** Having lightly diathermied the dura, a small hole is made in it and the ventricular catheter introduced and connected to a reservoir. With free flow from the distal end, the catheter is placed in the peritoneal cavity and the peritoneum closed snugly around it.

the abdominal opening, or vice versa. If a frontal burr hole is used, an intervening incision is made at the occiput.

The ventricular catheter is introduced mounted on a stylet. The trajectory is determined according to external landmarks or guided by neuronavigation. From an occipital burr hole, targeting the midpoint of the forehead at the hairline enables the occipital horn of the lateral ventricle to be entered. From a frontal burr hole, the target is the intersecting planes of the midpupillary line and the external auditory meatus. Intraoperative ultrasonography or image-guided stereotaxy[41] can be used for more accurate positioning of the catheter. CSF pressure can be measured once the ventricle is cannulated, and a sample of CSF taken for biochemical and microbiological examinations. The proximal catheter is connected to a reservoir and a valve system, itself connected to the tunneled distal catheter. The distal end is examined to ensure that there is free flow of CSF and then placed within the peritoneum. The peritoneum is closed followed by the rest of the abdomen in layers (Figure 97.4d).

VA SHUNTS

These may be performed in a similar fashion to VPSs except for the lower incision, which is over the right side of the neck. The objective is for the shunt tip to lie in the superior vena cava or atrium. Open access to the jugular vein can be achieved by exposing the common facial vein. This is tied proximally and held with a stay suture at the venotomy site, and the distal catheter is then fed into the superior vena cava. Throughout the procedure, the anesthetist monitors the electrocardiogram (ECG) for any cardiac alterations or rhythm changes. A purse-string suture is closed around the catheter sufficiently to prevent hemorrhage, but not so tight as to cause obstruction to the catheter. Percutaneous (Seldinger) methods can also be used to enter the jugular or subclavian veins, aided by ultrasound.[66–68] Complications include cor pulmonale, catheter emboli, and shunt nephritis.

VP SHUNTS

The proximal approach is identical to VPS placement. The pleural space can be entered safely in the fifth intercostal space along the anterior axillary line. Intercostal muscle layers are split on the upper border of the rib to avoid the neurovascular bundle. Once revealed, the parietal pleura is opened and the distal catheter gently introduced. The muscle is closed to avoid air entry into the pleural space. Intrapleural catheter placement may be aided by thoracoscopy.[65] Contraindications for this technique include previous thoracic surgery, acute or chronic pulmonary disease, and poor pulmonary function. Progressive CSF accumulation may lead to respiratory distress, and therefore, vigilance for this complication is important. This technique is rarely applicable in newborns, or indeed infants, as the pleural cavity has inadequate absorptive capacity at this age. The technique is usually reserved for older children where all other options have been exhausted.

Other sites for a distal catheter include the cerebral venous system, gallbladder, ureter, and bladder. These sites are used rarely in neonates because of their complexity and complications, leading to increased morbidity and mortality.

POSTOPERATIVE CARE

Postoperative scans are obtained and act as a reference for future surgery and shunt positioning. Continual monitoring of head circumference is required.

OUTCOMES

The outcome of hydrocephalus depends upon the underlying cause, the treatment selected (and complications thereof), the socioeconomic status of the child, and other factors beyond the scope of this chapter. The important message is that hydrocephalus is not a single disease entity and that treatment must be tailored to etiology and age. Avoidance of complications is of paramount importance and dramatically alters long-term prognosis.

Urinary tract infections

MARTIN KOYLE

INTRODUCTION

A urinary tract infection (UTI) is one of the most common bacterial infections diagnosed in childhood. This condition should be given strong consideration in the differential list when evaluating the febrile, ill neonate. The diagnosis of a UTI can lead to significant morbidity for the child, not only from the disease process itself but also from the formidable diagnostic evaluation subsequent to initial presentation. Given the premature immune system, infants, and particularly neonates, are at risk for disseminated bacteremia, which can lead to a more dangerous scenario than in older children and adults. Due to this associated danger, a thorough evaluation and prompt treatment when necessary are mandatory. In addition, the pediatric specialist needs to recognize that UTI may be a marker of a more serious, underlying urologic congenital and/or functional anomaly, which may be amenable to operative correction.

Potential urological sequelae from a UTI include renal scarring and compromised renal function, although such severe morbidity may be less likely than formerly perceived. Indeed, with the popularity of maternal fetal ultrasound (US) and antenatal detection of congenital anomalies, it is now well documented that such scarring is more often due to dysplasia. This is most obvious in the neonate with congenital vesicoureteral reflux (VUR). Regardless, it is still known that acquired renal scarring can occur in the vulnerable child, even when febrile UTI occurs and VUR is absent on radiological imaging. Current investigations are attempting to identify those specific groups at risk for renal damage. However, serious compromise of function is uncommon nowadays, especially when prompt treatment is instituted. Diagnostic tests recommended after a UTI vary, and recent guidelines have tried to help clarify the workup. Treatment, although benign and effective, has potential risks, in particular, the generation of resistant bacterial strains. Needless to say, a UTI carries with it a significant emotional and economic burden for the family of the sick child.

INCIDENCE

UTIs account for 0.7% of all pediatric office encounters and 5%–14% of pediatric emergency department (ED) visits in the United States.[6,10] Pediatric UTIs account for 1.8% of all hospitalizations in the United States, with costs for UTIs exceeding $520 million.[35] In addition, UTI has consistently been the most commonly diagnosed serious bacterial infection in the first months of life, with a prevalence varying from 1.8% to 7.5%. It is also the most consistently missed serious bacterial infection in studies attempting to define low-risk criteria for the evaluation of fever in the neonatal age group.[11] This unquestionably translates into a significant number of physician visits annually and/or extended hospitalizations of neonates, which add significantly to already escalating health care costs. It must be acknowledged that estimated costs do not include charges for subsequent evaluations, including clinic visits, follow-up studies, and time missed from work by parents.

Neonates represent a special subgroup with regard to UTI, with a male predominance of 2.5- to 6-fold, which is in striking opposition to the high prevalence rate of UTI among females in the over-6-months age group.[12] Overall, the reported incidence of neonatal UTI varies between 0.1% and 1% in the general population of healthy newborns.[2] In preterm neonates the incidence is much higher. Furthermore, this incidence is estimated at 10% in low-birth-weight infants.[10]

Reported prevalence in the preterm neonate ranges between 4% and 25%.[3] A meta-analysis of studies looking at prevalence of UTI in febrile children less than 3 months of age found that febrile female infants had a relatively high prevalence rate of UTI (5% in first 3 months). Uncircumcised males under 3 months had the highest rate at 20.1%, whereas circumcised males had the lowest rate (2.4%).[15]

ETIOLOGY

Numerous factors seem to predispose the child's urinary tract to infection. Most pathogenic bacteria that

cause UTIs arise from a reservoir in the intestinal tract. *Escherichia coli* is by far the predominant bacteria to cause UTI because of the unique ability of certain serotypes to adhere to the urothelium. One way of differentiating strains of *E. coli* is based upon differences in the antigens they elaborate on their polysaccharide capsule, which surrounds the bacteria. These antigens are known as K antigens, and it has been demonstrated that certain K antigenic *E. coli* have a much higher propensity for causing UTI than other strains.

Perhaps the most significant predictor of a bacteria's uropathic potential is its ability to adhere to the epithelial membrane where they cause infection—in the urinary tract, the urothelium. Pili or fimbrae are long filamentous appendages, composed of protein, that project from the bacterial surface and allow for this adhesion to take place. In *E. coli,* type 1 pili are highly associated with bacteria that cause UTI. Type 1 pili act to bind uroplakin, a protein cap that is elaborated by the umbrella cell or urothelial cell. Another form of pili, P pili, named for its ability to bind the P antigen of blood group antigens, is highly associated with strains of *E. coli* that cause pyelonephritis. Bacterial adherence, colonization, and subsequent UTI is a complex process that involves a balance between bacterial virulence factors and a host's immune response to invasive bacterial infection and colonization. Clearly, there are specific strains of enteric bacteria that cause UTI with a much higher virulence than many of the bacteria harbored in the gut. In addition, there are also individuals who are much more prone to UTI due to the complexity of the relationship between host and bacterial factors that allow adherence to first occur. Other uncommon organisms leading to newborn UTIs include *Klebsiella*, *Proteus*, *Pseudomonas*, and *Enterobacter* (Table 98.1).

P fimbriae *E. coli* adhere to the urothelial cells and lead to a decrease in ureteral peristalsis. Bacteria secrete endotoxins that cross the ureteral mucosa and lead to paralysis of ureteral smooth muscle along with risk of ascent and reflux of bacteria. Consequently, this slows the flow in the peripheral ureters, and adherent bacteria are not washed away. Compromise of host natural immune defenses that protect the urinary tract from infection, in particular, immunologic immaturity, also predisposes pediatric patients to development of UTI. In addition, some children will have colonization of their feces by virulent bacteria.[17] This is especially true in those patients with slow stool transit times and severe constipation, a cofactor that is more common in older children in the potty-training age group.

Table 98.1 Common uropathogens

Bacteria	Incidence
Escherichia coli	77%–93%
Klebsiella	0%–11%
Enterococcus	2%–9%
Serratia	~1%
Staphylococcus aureus	~1%
Pseudomonas aeruginosa	~1%
Enterobacter cloacae	~1%
Streptococcus	~1%
Proteus	~1%

PRESENTATION

In neonates, the most common clinical presentation varies and is less classical than in older children and adults. Symptoms such as fever, irritability, food intolerance, respiratory distress, and jaundice are common; in premature infants, symptoms encountered may be even more nondescript or non–urinary tract specific, including feeding intolerance, apnea, bradycardia, lethargy, and abdominal distention.[7] Rarely will symptoms referable to the urinary tract, such as hematuria and foul-smelling urine, be observed in the neonate. Given this diagnostic dilemma, many UTIs are either not diagnosed or diagnosed late; some are undoubtedly missed or treated as another entity. Primary care providers must have a high index of suspicion for UTI in the neonatal period to achieve an accurate diagnosis and of course obtain a properly collected urine specimen.[21]

Additional concerns of the practitioner lie in the knowledge not only that risk of serious bacterial illness is higher in young infants and neonates, but also that the clinical clues that are often used to detect serious illness are not reliable. Clinical illness indicators such as state variation and reaction to parental stimulation are not reliable predictors of serious illness. As many as 65% of neonates with a febrile illness involving a serious bacterial infections appear well on initial examination.[18]

Clinical manifestations of neonatal UTI can be similar to clinical signs of neonatal sepsis, although digestive symptoms have been reported to be more frequent in newborn infants. Elevation of body temperature and poor feeding were the most frequent clinical symptoms, in particular in infants with community-acquired infections. Children younger than 3 months with a UTI are more likely than older children to have bacteremia, sepsis, and congenital genitourinary abnormalities.[6] Bacteremia associated with UTIs is mostly observed in patients <6 months of age, particularly those <2 months of age, whose risk of bacteremia is estimated between 4.0% and 22% (Table 98.2).[1]

IMPACT OF CIRCUMCISION

As we debate the medical indications for circumcision in this country, it is well documented that newborn uncircumcised males are at higher risk for UTIs. Uncircumcised boys have an overall 12-fold increased risk of UTI compared with circumcised boys during the first 6 months of life.[14] The benefit of circumcision in terms of UTI prevention is known to extend for 6 months after birth, and possibly for as long as 1 year. After 1 year of age, there is no evidence that circumcision affects the rate of UTI in males.

Table 98.2 Prominent symptoms in neonatal nonobstructive UTI

% Symptom	Prevalence (%)
Failure to thrive/weight loss	51
Fever	41
Jaundice	12
Cyanosis	30
Vomiting	35
Diarrhea	20

Source: Modified from Phol HG, Rushton HG, Urinary Tract Infection in Children, in *The Kelalis–King–Bellman Textbook of Clinical Pediatric Urology*, Docimo SG et al., eds, Informa, UK, 2007, 103–166.

Uncircumcised boys younger than 6 months have a greater quantity of both *E. coli* and Gram-negative uropathogens in their urethras as compared with circumcised cohorts. Voiding pressures in newborn males are higher on urodynamic evaluation. Higher voiding pressures, along with a higher risk for cystitis and colonization, amount to an increased propensity for illness in these children. Total costs for treating UTI are reported to be 10-fold higher in uncircumcised than in circumcised male infants, which reflects the greater number of UTIs diagnosed in this patient group and possibly a higher number of hospital admissions.[9] Findings confirm the strong body of evidence attesting to the protective effect of newborn circumcision against UTI in the first year of life, an age when infections are most severe and likely lead to hospital admission.[9] Still, there is morbidity to this procedure, and it is estimated that the number needed to treat is approximately 111; that is, 111 boys need to undergo circumcision in order to prevent 1 UTI.[34]

BREASTFEEDING

Breastfeeding may have a protective role in preventing UTI in premature infants and should be encouraged.[7] Breastfeeding has been significantly associated with a lower risk of UTI. It has been reported to have a protective effect against many infections in the first year of life, including gastroenteritis, acute otitis media, pneumonia, bacteremia, and meningitis. The protective effect is attributed to its action on the intestinal flora, including its high concentration of IgA, which inhibits adherence of bacteria. In addition, lactoferrin prevents the growth of intestinal *E. coli*. Furthermore, the low pH of stool in breastfed babies allows for the growth of and colonization with less virulent organisms such as bifidobacteria and lactobacilli.[7]

DIAGNOSIS

Unlike older children, neonates lack diurnal temperature variation and have less normal temperature variability. During an acute infection, fever is commonly absent in neonates.[8] The general appearance and physical examination of the febrile neonate cannot be relied on to exclude a serious bacterial infection. Multicenter prospective studies of febrile infants who were 60 days of age or younger and evaluated in an emergency room for fever, circumcision status, and height of fever were associated with an increased likelihood of UTI.[11] Hyperbilirubinemia with prolonged jaundice (lasting more than 14 days) is commonly the main clinical feature at presentation, which may be the only manifestation of UTI.[2] Jaundice can be an early sign in afebrile infants, and was more common with in those neonates with nosocomial UTI. Positive urinalysis findings have been reported in approximately 56% of cases.[3]

The most common current ED practice management of even a well-appearing febrile neonate is a full sepsis evaluation, including a complete blood count (CBC), blood cultures, urinalysis and urine culture, evaluation of cerebrospinal fluid (CSF), and administration of antibiotics (ampicillin, cefotaxime, or gentamicin) with hospitalization pending culture results.[20] The initial evaluation must include a detailed history along with a thorough physical exam. Care must be taken when evaluating the newborn for abdominal masses. The back must be carefully examined for the presence of dimples or abnormalities suggestive of a spinal dysraphism. The degree of phimosis should be noted if the child is uncircumcised, and although rare, labial adhesions must be ruled out in female newborns. The presence of adhesions and recurrent UTI is an indication for intervention. In neonates, adhesions are treated surgically in order to avoid the utilization of estrogen or betamethasone ointments, which are commonly recommended in older children (older than 6 months of age).

The definitive diagnostic test of a UTI is a positive urine culture. This can be obtained through suprapubic aspiration or urethral catheterization. A false-positive culture obtained via a bag specimen may lead to inappropriate treatment, misdiagnosis, and unnecessary testing. The urinalysis, which is immediately available, is suggestive but not diagnostic. Although the presence of leukocyte esterase has a high sensitivity, it lacks in specificity; conversely, the nitrate test behaves oppositely. When combined with microscopic findings, the sensitivity approaches 100% when all three are positive, and the specificity is 100% when all three are negative.[16] The presence of any bacteria on Gram stain has a sensitivity of 93% and specificity of 95%, better than dipstick evaluation for leukocyte esterase and nitrates.[21]

There are four ways that urine can be obtained for specimen. First, a bagged specimen involves a plastic bag that is taped to the perineum and urine obtained after the child voids. This can be useful in infants, but there is a high risk of obtaining a contaminated specimen. Second is a midstream collection, which is unreliable in children, especially in young girls and uncircumcised boys in whom contamination is likely. This is useful if negative, but if positive, it is hard to tell if the collection was

contaminated. Third, a catheterized specimen is more invasive and possibly traumatic in children. In the uncooperative girl, it can easily be contaminated. However, for the non-toilet-trained child, it is the most reliable and effective way to obtain a specimen. Lastly, a suprapubic bladder aspiration is the least likely to be contaminated. Again, it is invasive and rarely practiced in the current litigious environment.[21]

In neonates less than 3 months old, a catheterized urinalysis or suprapubic bladder aspiration is part of the standard workup for fever. Suprapubic aspiration, although not usually necessary, is considered the gold standard method for obtaining urine. It is performed after cleaning the suprapubic area with antiseptic solution. A 21- to 25-gauge needle is inserted one fingerbreadth above the symphysis pubis perpendicularly while aspirating until urine is obtained. Although suprapubic aspiration is popular in some EDs, it is invasive and has variable success rates for obtaining urine because of the lack of urine in the bladder. Physical examination to palpate for a full bladder is sometimes limited if the child is very upset. US, if available, may be useful to check bladder fullness before aspiration. For males with phimosis or stricture, and for girls with severe labial adhesions, suprapubic aspiration may be the only method for obtaining clean urine.[24] Although the probability of a true infection with a positive culture obtained via suprapubic aspiration is approximately 99%, this method is the most technically challenging and is associated with the lowest rate of success (23%–99%).[4]

For recovery of any organism from a suprapubic specimen, at least 50,000 colony-forming units per milliliter (CFU/mL) from a catheterized specimen or at least 100,000 CFU/mL from a clean-catch specimen is considered significant bacteriuria.[6] We should reemphasize the importance of accurate diagnosis and the appropriate collection of specimen. Results affect the child's care and can potentially subject him/her to invasive procedures, while possibly contributing to parents' undue stress. The American Association for Pediatrics (AAP) has published recommendation for diagnosis, treatment, and evaluation of initial UTI in febrile infants and young children; however, no recommendations for neonates <2 months old have been suggested.[3] Investigators have commented on the value of urine smell in the diagnosis of UTI. A study by Struthers et al. demonstrated no association between reported abnormal or different urine smell and UTI.[5]

C-reactive protein (CRP) >20 mg/L, erythrocyte sedimentation rate (ESR) >30 mm/hour, and white blood cell (WBC) count >15,000/μL are key findings in various studies on febrile infants. The diagnostic value of these for predicting serious bacterial infection in febrile infants, however, is conflicting. Lin et al.[19] showed that febrile infants with CRP >20 mg/L and ESR >30 mm/hour were at risk for UTI but that a WBC count >15,000 was not significantly associated with UTI. Although the specificity of ESR and CRP was high, their sensitivity was relatively low, demonstrating that elevated CRP and ESR are poor predictors for identifying UTI in febrile illness.

Recent guidelines have been released by the AAP on the diagnosis and management of the febrile infant. An algorithm for clinical practice can be seen in Figure 98.1.

MANAGEMENT

Developmental considerations exist that must be taken into account when treating neonates with a UTI. Glomerular filtration rate is low at birth and develops with age. This must be taken into consideration when prescribing medication and calculating fluid requirements.[10] Treatment depends on the diagnosis of either cystitis or pyelonephritis, and whether the diagnosis is simple or complicated. Simple cystitis requires a short course of oral antibiotics based of susceptibilities (3-day course). A complicated UTI will require a longer course and even parenteral antibiotic administration based on initial presentation. Pyelonephritis requires a 10- to 14-day course of parenteral medication followed by oral administration based on initial presentation. It has been established that oral and intravenous antibiotics have been equally effective in treating young children with acute pyelonephritis. It was shown that acutely, time to defervescence and return to sterile urine within 24 hours was identical, not to mention that the cost of a 10-day oral course was significantly lower, without clinical compromise, i.e., reinfection or renal scarring.[28] Studies evaluating the treatment of febrile UTIs in young children with oral versus intravenous antibiotics have demonstrated similar efficacy with the use of third-generation cephalosporins.[23]

The antibiotic repertoire available to the physician in the newborn period is significantly more limited than that available for older children. Aminoglycosides, penicillins, and cephalosporins can be utilized in the newborn period; however, their use is not without risk. Potential complications associated with their use include diarrhea, intolerance, and allergic reactions including anaphylaxis as well as nephrotoxicity if not carefully dosed and monitored. Nitrofurantoin has been linked to hemolytic anemia in the neonatal period and should not be utilized in children with glucose-6-phospate dehydrogenase deficiency, because of the risk of hemolysis. Given low tissue penetration levels attained during administration, nitrofurantoin is a poor choice for the treatment of pyelonephritis. Trimethoprim use should be avoided in patients with megaloblastic anemia and folate deficiency or in children with sodium wasting disease (i.e., posterior urethral valves [PUVs] or renal insufficiency) because of potential hyperkalemia from blocking the sodium channels present in the principal cells of the cortical collecting ducts. It can also increase serum creatinine levels by blocking the proximal tubular secretion of creatinine. Trimethoprim/sulfamethoxazole should not be used in newborn period, because of concerns for hyperbilirubinemia and

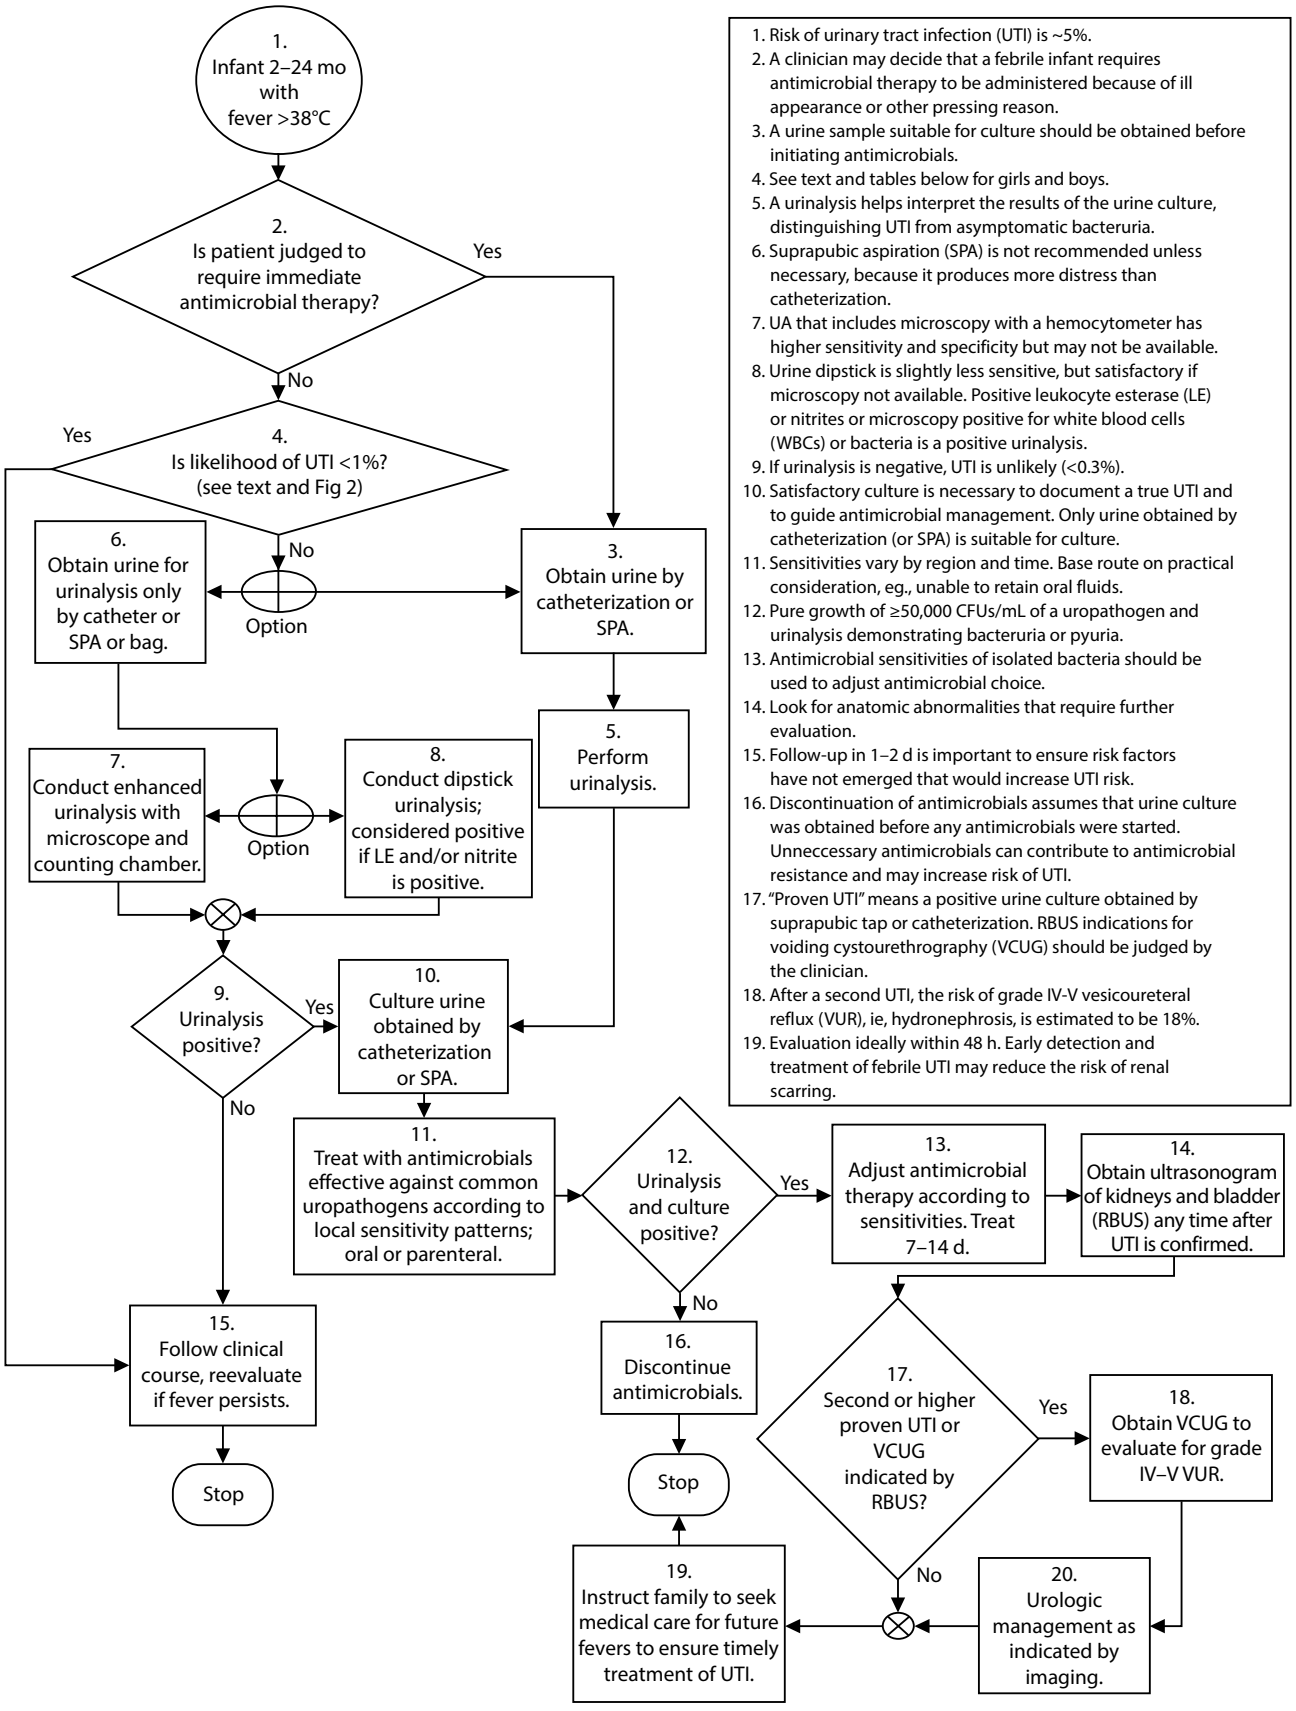

Figure 98.1 Algorithm for treating infants with unexplained fever. (From American Academy of Pediatrics, Committee on Quality Improvement, Urinary Tract Infection: Clinical Practice Guideline for the Diagnosis and Management of the Initial UTI in Febrile Infants and Children 2 to 24 Months, *Pediatrics* 2011; 128(3): 595–610.)

kernicterus. The metabolic acidosis seen in patients taking trimethoprim/sulfamethoxazole is attributed to bicarbonate loss induced by the sulfamethoxazole component through an acetazolamide-like effect on the proximal tubules.[22]

VESICOURETERAL REFLUX

Prenatal hydronephrosis is noted in 1%–5% of pregnancies. The prevalence of VUR in neonates varies from 11% to 12.5%. Considering fetal and postnatal renal pelvic anteroposterior diameter (APD) as a combined test, a value of less than 10 mm is a negative indication for a voiding cystourethrogram (VCUG). This results in increased sensitivity and diagnostic odds ratio for detecting clinically significant VUR.[33] The likelihood of significant renal abnormalities postnatally correlates with the severity of APD dilation. A meta-analysis of 17 studies reported the risk of renal abnormalities for three classifications of antenatal hydronephrosis. The probability of ureteropelvic junction obstruction increased, but there was no association of VUR with APD measurement (Tables 98.3 and 98.4).[32,37]

The incidence of VUR in children presenting with symptoms of a UTI is in the order of 30%–50%. The incidence, however, is believed to be lower in neonates. Standard of care calls for antibiotic prophylaxis in a child presenting with a febrile UTI, or recurrent nonfebrile UTIs, until VUR can be ruled out. Traditionally, recommended workup has consisted of a renal and bladder US as well as a VCUG, or a nuclear medicine cystogram, both of which are invasive studies. The false-negative rate of VCUG is estimated at 20%. A nuclear medicine cystogram involves a fraction (1%) of the radiation exposure experienced with a VCUG. Although its sensitivity is excellent, one major disadvantage is the lack of anatomic detail. It is difficult to identify Hutch diverticula, bladder trabeculation, or a dilated posterior urethra with a nuclear medicine study.

A dimercaptosuccinic acid (DMSA) scan at the time of presentation is the hallmark of the *top–down* approach.

Table 98.3 Degree of prenatal hydronephrosis and postnatal risk of renal abnormalities

Degree of hydronephrosis	Postnatal risk
Mild <7 mm in second trimester <9 mm in third trimester	11%
Moderate 7–10 mm in second trimester 9–15 mm in third trimester	45%
Severe >10 mm in second trimester >15 mm in third trimester	88.3%

Table 98.4 Prenatal hydronephrosis and risk of postnatal VUR

Degree of hydronephrosis	Postnatal risk
>12 mm at 20 weeks and >14 mm at 34 weeks	15%
6–8 mm during second or third trimester	5%

Source: Hothi DK, Wade AS, Gilbert R, Winyard PGT. Mild Fetal Renal Pelvis Dilatation—Much Ado About Nothing? *Clin J Am Soc Nephrol* 4: 168–177, 2009.

Some authors advocate that 50% of children will have a positive DMSA during the acute phase. Out of those children, 30%–40% will demonstrate reflux. Conversely, 90% of children with VUR will have had a positive DMSA scan. If VCUG is deferred for those children with febrile UTI and a positive acute DMSA scan, presence of hydronephrosis, or a dilated ureter, one would miss 10% of children with VUR, the majority of these being children with low-grade VUR, low risk for UTI, and late renal scarring.[27] Small studies looking into early DMSA scanning in neonates, mainly females and uncircumcised males, agree that DMSA is helpful in ruling out later development of permanent renal damage but was not predictive of the absence of dilating VUR. Therefore, if dilating VUR is to be ruled out, a VCUG needs to be performed even in the presence of a normal DMSA scan.[29] Neonatal reflux, even high grade, is more likely to resolve than VUR detected after UTI at a later age. Prospective data on the follow-up of infants with prenatal hydronephrosis diagnosed with grade III, IV, or V showed resolution rates of 53%, 28%, and 40%, respectively, at 4 years.

The goal of radiologic studies is to identify genitourinary malformations and defects that can predispose the newborn to recurrent UTI. Anatomic obstruction (PUVs, ureteropelvic junction obstruction, ureterovesical obstruction, and ureterocele) as an etiology for UTI is seen in 2%–10%.[13] Urethral obstruction during fetal development secondary to anatomic reconfiguration of the bladder neck is suggested as the cause of high-grade bilateral reflux in male neonates.[22] Hoberman et al.[30] evaluated the value of renal US after the first febrile UTI in children as young as 1 month. Their conclusion was that less than 1% of renal US after a first febrile UTI will show findings significant enough to impact management, including additional imaging studies. In their conclusion, the authors did not recommend ultrasonography after a first febrile UTI in children with an unremarkable prenatal US after 30–32 weeks of gestation. In a study of early DMSA scanning in neonates with febrile UTIs, Siomou et al.[31] found that the ability of DMSA to predict dilating VUR was low, since the majority of children with >grade III VUR had normal DMSA results. Moreover they noted that of these patients, all were noted to have a normal renal US.

AAP Imaging Guidelines

- Febrile infants with UTIs should undergo renal and bladder ultrasonography.
- VCUG should not be performed routinely after the first febrile urinary tract infection (fUTI); VCUG is indicated if renal-bladder ultrasound reveals hydronephrosis, scarring, or other findings that suggest either high-grade VUR or obstructive uropathy, as well as in other atypical or complex clinical circumstances.
- Further evaluation should be conducted if there is a recurrence of fUTI.

Source: American Academy of Pediatrics, Committee on Quality Improvement, Urinary Tract Infection: Clinical Practice Guideline for the Diagnosis and Management of the Initial UTI in Febrile Infants and Children 2 to 24 Months, *Pediatrics* 2011;128(3):595–610.

PROPHYLAXIS

The benefits from prophylactic antibiotic use have been debated, including their use in those children with VUR and those without it. Four large clinical studies have indicated no benefit of prophylaxis versus observation; however, few patients included in the studies had high-grade VUR. The Australian Prevention of Recurrent Urinary Tract Infection in Children with Vesicoureteral Reflux and Normal Renal Tracts (PRIVENT) study suggested a benefit to prophylaxis reducing incidence of UTI recurrence. Fifteen children had to be treated for 12 months to prevent a single UTI. Circumcision status, however, was not discussed in this study.[25,26] Results from the Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) trial demonstrated that prophylactic antibiotics reduced the recurrence rate of UTI (12.9% on prophylaxis vs. 23.6% on placebo), with an increase in resistance rate of 63% on prophylaxis versus 19% on placebo. While not appropriately powered to fully evaluate, there was no significant difference found in new renal scarring between placebo and prophylaxis.[36]

The use of antibiotic prophylaxis must be a partnered decision between the practitioner and the patient, considering the risks and benefits. One must remember that surveillance is not equivocal to nontreatment; however, it requires that the family be educated on signs and symptoms of a UTI and the importance of prompt evaluation and treatment (Table 98.5).

Table 98.5 Prophylactic antibiotic regimens for prevention of UTI

Antibiotic	Daily dosing
Trimethoprim	2 mg/kg
Trimethoprim sulfamethoxazole (TMP-SMX)	2 mg/kg TMP 10 mg/kg SMX
Nitrofurantoin	1–2 mg/kg
Amoxicillin	20 mg/kg
Cefixime	4 mg/kg

SURGERY

Surgical intervention in the newborn for recurrent UTI is rarely necessary. Indications for surgery include recurrent episodes of UTI and/or deteriorating renal function noted on nuclear medicine studies (Table 98.6). Infection in the face of hydronephrosis from a ureteropelvic junction obstruction mandates consideration for surgical reconstruction. Surgery can also be considered for ectopic ureteral insertion and distal ureteral obstruction with recurrent infection, with or without antibiotic prophylaxis. The size of the newborn bladder has to be taken into consideration during reconstruction, given that a ureteral reimplantation into a small newborn bladder can be technically challenging. Some authors advocate the utilization of proximal or distal diversion in order to allow the bladder time to grow and attain a larger capacity. Staged repairs can be considered especially if there is the potential need for tapering of the distal ureter during reimplantation. The presence of a ureterocele and infection calls for prompt incision followed by antibiotic prophylaxis given the high likelihood of VUR. Ureterocele puncture or incision is usually followed by reconstruction of the bladder.

Since its approval by the Federal Drug Administration, dextranomer/hyaluronic acid (Dx/HA) copolymer has revolutionized the management of VUR. Its applicability to newborns has not been well documented. However, given the low morbidity associated with this procedure, injection therapy is a viable option in the face of recurrent UTIs and low-grade VUR. It should be noted, however, that injection into a newborn bladder can be challenging, and long-term follow-up studies after injection in younger children are lacking.

UTIs in the myelodysplastic newborn warrant earlier urodynamic evaluation, the implementation of anticholinergic therapy, and clean intermittent catheterization, along with the use of prophylactic antibiotic therapy. Recurrent infections may require surgical intervention in the form of vesicostomy and, rarely, more proximal diversions such as ureterostomy or pyelostomy. Recurrent infections following ablation of PUVs and persistent hydronephrosis can also lead to diversion including the use of ureterostomy or pyelostomy to prevent recurrent infections. Prior to diversion in the PUV patient, imaging studies (such as VCUG) should be obtained confirming that the valves have been

Table 98.6 Surgical conditions leading to febrile UTI

Anatomic	Functional
Vesicoureteral reflux	Neurogenic bladder
Ureterocele	Myelomeningocele
Ureteropelvic junction obstruction	Dysfunctional voiding
Posterior urethral valves	Hinman syndrome
Obstructed megaureter/ megacalicosis	
Ureteral or renal calculi	

adequately ablated. A thorough urodynamic evaluation is also recommended. However, in the authors' opinion, the use of diversion rarely affects the clinical course of the patient and rarely seems to affect the recurrence rate.

CONCLUSION

Neonates are particularly susceptible to developing UTIs, which may be explained by the compound effect of immaturity of the local defense mechanisms (decreased uroepithelial bactericidal activity, low levels of local immunoglobulin A, decreased urinary acidification) and heavy periurethral colonization occurring in healthy neonates and gradually resolving after 6 months of age.[12] The benefit of circumcision in the prevention of early urinary tract infection is not questionable in the neonate. In the general population, the recurrence rate for UTI is very high. Within 1 year of a first infection, approximately 30% of boys and 40% of girls will develop a repeat infection. The rate will double for each subsequent episode.[13] Unfortunately, recurrence is not uncommon in the neonatal period. With the widespread use of prophylactic antibiotics, recurrence with multiresistant organisms is also a possibility. The need and extent of radiologic imaging required following a neonatal UTI are still under investigation. The usefulness of invasive, expensive studies continues to be questioned.

Pediatric UTIs constitute a significant health burden; although the actual costs are not known, it is estimated to be in the order of $180 million for inpatient costs in the United States. This fails to include the costs to society of parental productivity from lost wages, treatment, and follow-up after the infection.[21] There are a number of complex host and bacterial virulence factors that play into susceptibility of children to UTI. It is important that the clinician be familiar with the spectrum of UTI, and children at risk of UTI, so infants and children who need to be evaluated for anatomic or functional abnormalities of the urinary tract are correctly identified and managed.

Imaging of the renal tract in the neonate

MELANIE HIORNS AND LORENZO BIASSONI

INTRODUCTION

The widespread use of antenatal ultrasound (US) in the last 25–30 years has allowed the early identification of a number of congenital nephrourological abnormalities, which are now assessed with imaging soon after birth. In addition, a congenital nephrourological abnormality may declare itself postnatally, for example, with a urinary tract infection, anomalies in urine stream, septicemia, metabolic upset due to renal failure, or simply vomiting. Occasionally, the neonate may have hematuria due to renal vein thrombosis, especially in the case of a prolonged labor with hypoxic events. A healthy neonate may present with an abdominal mass found on routine examination or with an apparently unrelated congenital abnormality, e.g., esophageal atresia.

Once the attention of the clinical team has been focused on the genitourinary tract, the role of the radiologist is to establish whether the child has been born with a normal urinary tract and he/she is therefore suffering from an acquired condition, or whether he/she suffers from a congenital anomaly.

Usually, the questions asked by the clinical team are the following: (1) How many kidneys are present, and where are they within the abdomen? (2) Is there dilatation of the renal collecting system, and is the renal parenchyma normal or abnormal? (3) Are the bladder and the urethra normal, or is there a thick-walled bladder and/or an obstructed urethra? (4) What is the renal function, both in absolute terms and in terms of the split function of each kidney?

The radiologist has four key imaging examinations available, which can provide an answer in the vast majority of cases: abdominal US, micturating cystogram (MCUG), radioisotope examinations, and magnetic resonance imaging (MRI). Nowadays, there is absolutely no indication for intravenous urography (IVU) in the neonatal period (and almost no role in the older child), and it is considered obsolete. Computerized tomography (CT) in the neonatal period would be confined exclusively to the assessment of a renal mass if the US had not been able to provide satisfactory information and if MRI was not available. However, there are very few instances when MRI is not available locally or in a specialist center, and CT should therefore be considered a modality of last resort. MRI has an important role to play in the workup of renal tumors and in the assessment of the morphology of the urinary tract, again, if insufficient information has been obtained by US. In this instance, most newborn babies can undergo a "feed-and-wrap" technique and will not necessarily require sedation or a general anesthetic, although this will be needed in older infants or in neonates or infants needing breath-hold sequences.

COMMONLY AVAILABLE IMAGING MODALITIES

Abdominal US

The first imaging examination of the urinary tract should always be an abdominal US. With modern US equipment and well-trained personnel, it is possible to obtain anatomical detail of the entire urinary tract. The equipment is mobile, and a comprehensive US examination can be undertaken even in the ill neonate in an incubator on intensive care. The results of the US examination set the framework of the anatomical state and frequently permit the nephrourological team to begin therapy with either a short list of differential diagnoses or a presumed single diagnosis. In the majority of cases, the US examination will identify how many kidneys are present, the renal size, whether the kidneys are simplex or duplex, if the parenchyma is sonographically normal, and if there is dilation of the renal collecting systems. The bladder should be examined at the beginning of the US examination, as micturition may occur at any moment and a full bladder is useful when searching for dilated ureters behind the bladder (Figure 99.1). Bladder wall thickness is easy to identify and measure; the proximal posterior urethra may be dilated in the male with posterior urethral valves, and this can be identified during micturition if looked for. The patient needs no preparation for a

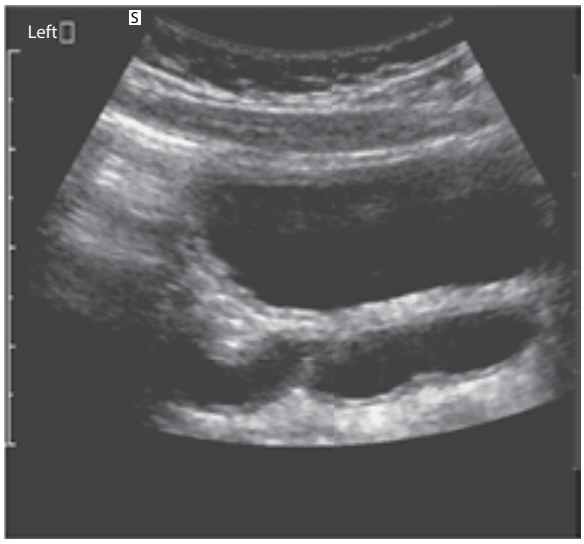

Figure 99.1 Ultrasound showing a dilated left ureter behind the bladder. In this patient, this was secondary to a vesicoureteric junction obstruction.

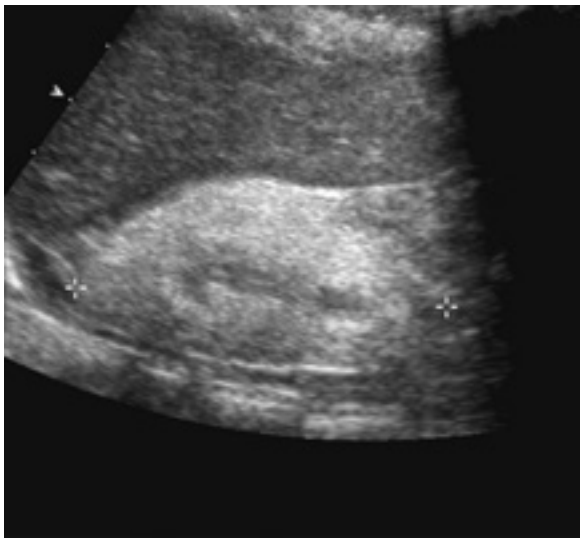

Figure 99.2 Ultrasound in a newborn male patient with primary hyperoxaluria. The kidney is echo-bright compared to the adjacent liver and has lost its corticomedullary differentiation, and in this condition, the brightness represents global nephrocalcinosis.

Figure 99.3 Ultrasound in a 4-week-old male patient with congenital nephrotic syndrome. The kidney is bright and enlarged, but some of the normal architecture can still be recognized.

US examination. The examination should be performed with both the standard curvilinear probe and also with a high-frequency (and thus high-resolution) linear probe. Ideally the infant should be scanned both supine and prone, although if a neonate is being ventilated, it will not be possible to obtain prone images.

The normal US appearance of the kidney in a neonate is of a slightly echo-bright cortex, when compared to the adjacent liver or spleen, with a slightly echo-poor medulla (pyramids). The difference between the cortex and the medulla is termed corticomedullary differentiation. A small kidney with loss of corticomedullary differentiation indicates an abnormal parenchyma (Figures 99.2 and 99.3). This may be due to an acute insult such as acute renal failure or renal vein thrombosis or may represent an underlying intrinsic abnormality such as renal dysplasia, which may be associated with cysts (or not) to varying degrees. The presence of dilatation of the collecting system must raise the possibility of obstruction but does not necessarily infer this. If the dilatation is bilateral, then bladder outlet pathology must be excluded. However, vesicoureteric reflux (VUR) may give a very similar appearance.

In the neonate, features on US of echogenic areas within the kidneys may suggest nephrocalcinosis (Figure 99.2), and this is the most common cause of focally echo-bright kidneys following furosemide diuretic therapy. Tamm–Horsfall proteins may give a similar appearance but are transitory.

There are two important pitfalls that must be stressed with US. The first is in the presence of a sick neonate who is either anuric or oliguric, when US may not reveal any dilation but an obstructive uropathy may still be present. In this clinical situation, a repeat US must be carried out once the infant starts to produce urine. The second pitfall is in the case of antenatally diagnosed unilateral hydronephrosis: here, the US may fail to show significant dilation during the first 48 hours of life due to physiological dehydration, and the US should be done on the third postnatal day or later.

Micturating cystourethrogram

A micturating cystourethrogram (MCUG) gives invaluable anatomical information about the bladder, and the bladder outflow tract in the male, and if VUR is detected, then details of the ureters, pelvis, and calyces are well outlined (Figure 99.4). Contrast showing calyceal detail may suggest

Figure 99.4 Micturating cystourethrogram in a patient with gross reflux outlining the hydroureteronephrosis and the configuration of the collecting system. There was no outflow tract obstruction in this patient (no posterior urethral valve).

renal dysplasia. The combination of US and MCUG allows adequate evaluation of all kidneys and collecting systems shortly after birth and permits appropriate management to be instituted immediately in all cases, especially if an obstructive uropathy is present, e.g., posterior urethral valves (Figure 99.5). The timing of the MCUG will depend on the clinical presentation and clinical state of the baby.

The baby will need to be catheterized, and in most patients, a 6F feeding tube can be used. It is not necessary to use a catheter with a balloon as there is no indication to inflate the balloon for this study, and indeed, inflating the balloon may/will cause bladder outlet obstruction and thus must not be done. The voiding views of the urethra in the male child should be obtained both with the tube still in and with it removed to ensure that a tiny valve leaflet is not missed as a consequence of being flattened by the presence of the catheter. Antibiotic cover should be given before and after the procedure (in accordance with local/national guidelines), and the procedure should be done under sterile conditions.

An MCUG is only rarely indicated in the immediate neonatal period, although there may be extended indications when the infant is slightly older. In the neonatal period, it is most commonly indicated with the US finding of bilateral hydronephrosis. This raises the possibility of an obstructive uropathy in the urethra (posterior urethral valve in the male infant), at the bladder base (ureterocele), or at the vesicoureteric junction (VUJ) bilaterally, or a bilateral pelviureteric junction (PUJ) obstruction. Bilateral VUR may give identical images (Figure 99.4). In this context, an MCUG should be carried out as soon as the baby is in a good clinical state.

If an MCUG is being performed for possible posterior urethral valves and these are confirmed, then the catheter should *not* be removed; the diagnosis has been established, there is no additional information to be gained by a tube-out view, and there is a risk of a difficult recatheterization to reestablish continued bladder drainage.

The neonates with an antenatal diagnosis of hydronephrosis requiring an MCUG include all those with postnatal US confirmation of a dilated ureter, bilateral hydronephrosis, or an abnormal bladder. Unilateral hydronephrosis with a normal opposite kidney and bladder on US in a well neonate does not require an MCUG.

If the clinical question is only about the presence of VUR, and the anatomy of the urethra in a male infant has already been assessed with a previous MCUG, a radioisotope cystogram (direct isotope cystography [DIC]) will answer the question, with a negligible radiation burden (less than a chest x-ray) to the infant. This test is obtained by positioning the child on the gamma camera head and catheterizing the bladder. A minimal amount of Tc-99m pertechnetate (20 MBq is sufficient) is then instilled in the bladder via the catheter. The catheter is connected to a bag with saline; the saline is run, and the bladder is filled until the child feels the urge to void. The acquisition begins after instilling the tracer in the bladder and continues until the end of the emptying phase (or when VUR has been demonstrated). If there is VUR during the bladder-emptying phase, this will be detected with high sensitivity (Figure 99.6).

Functional imaging

Radioisotope examinations provide an in vivo evaluation of the global and regional renal cortical function, with a precise estimate of the contribution of each kidney to the total renal function. Moreover, the dynamic radionuclide shows how each kidney drains, with identification of possible holdups.

TRACERS AVAILABLE

The main tracers available are the Tc-99m dimercaptosuccinic acid (DMSA), the Tc-99m mercaptoacetyltriglicine (MAG3) and the Tc-99m diethylenetriaminepentacetic acid (DTPA). Some centers use I-123 orthoiodohippuran (OIH), but the labeling with I-123 (cyclotron produced) makes it an expensive and not readily available tracer. The DMSA is taken up by the proximal renal tubules, and once in the renal parenchyma, approximately 60% sticks within the tubules, while approximately 30%–40% of the tracer leaves the kidney with the urine. DMSA is the current gold standard for the evaluation of the differential renal function (DRF) and the evaluation of renal parenchymal integrity. The MAG3 and the OIH are secreted by the proximal tubules into the lumen and leave the kidney via the collecting ducts and the renal collecting system. The DTPA is filtered by the glomerulus and leaves the kidney via

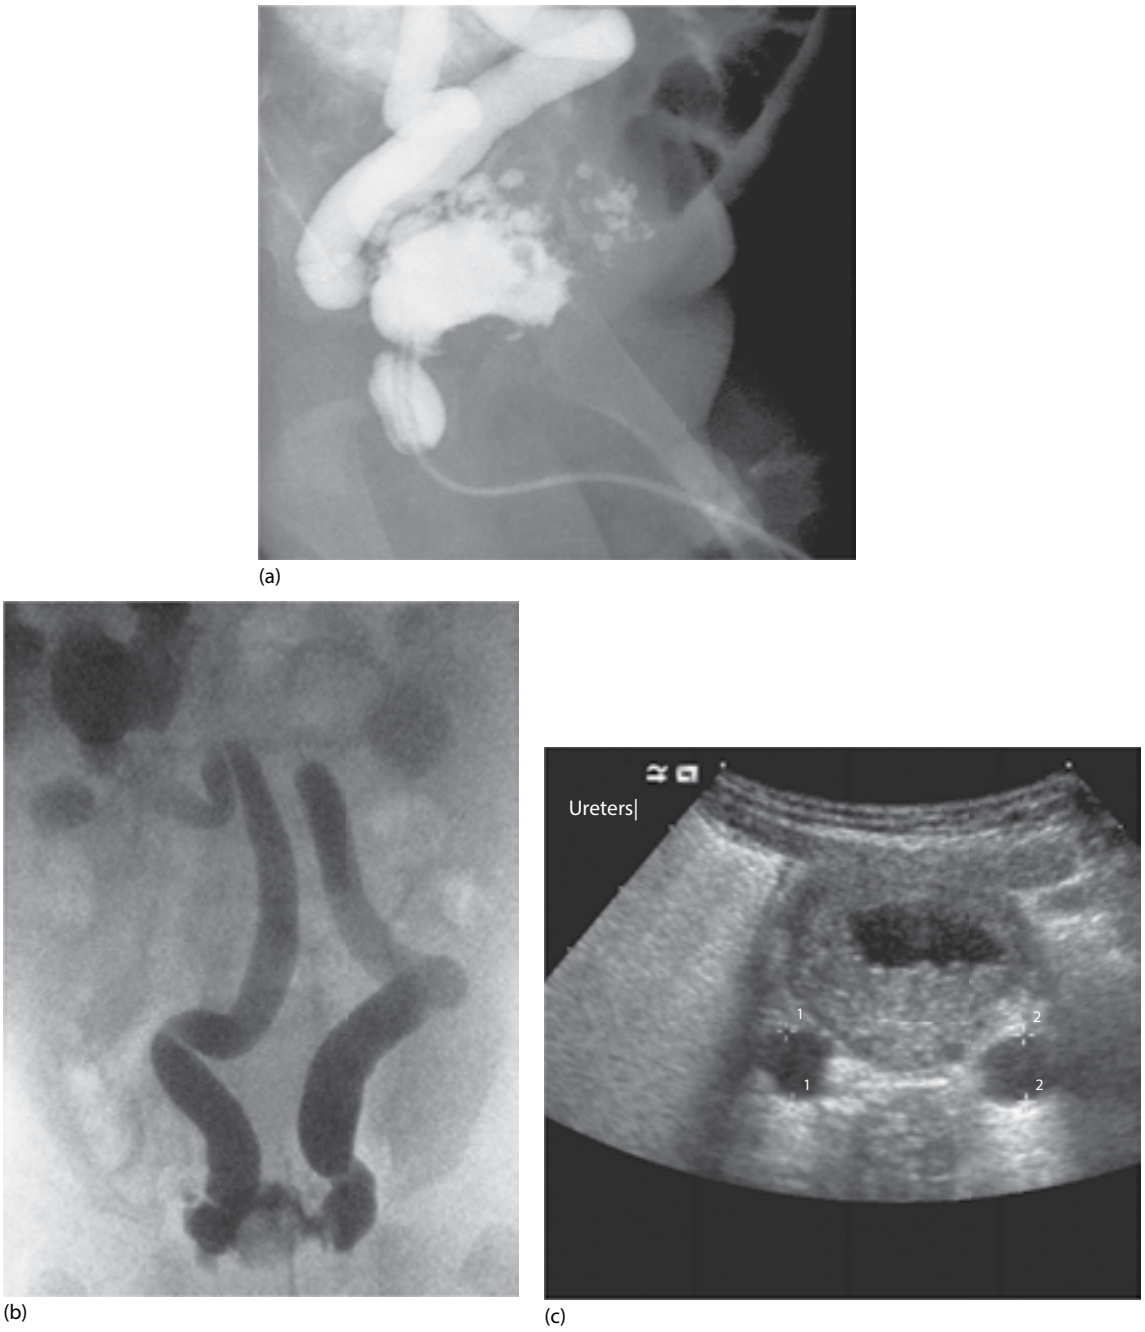

Figure 99.5 **(a)** Micturating cystourethrogram in a newborn male demonstrating a tight posterior urethral valve and a very trabeculated and thickened bladder wall. **(b)** A later view in the same patient showing gross reflux in both ureters to the level of the collecting systems. The bladder has preferentially refluxed contrast into the upper tracts as this presents less obstruction than overcoming the tight posterior urethral valve. **(c)** Ultrasound in the same patient showing a very thick-walled bladder and bilateral dilated ureters behind the bladder.

the collecting system. Tc-99m MAG3 has a higher extraction fraction than Tc-99m DTPA and therefore is a better tracer, especially in the neonate. The tracers used for dynamic renography can evaluate DRF almost as accurately as the DMSA. They can also provide an evaluation of renal parenchymal integrity (small scars can be missed though) and assess drainage.

Static renal scintigraphy

The DMSA scan requires the acquisition of high-quality static images in order to be clinically useful. The child has to be immobile during the acquisition process. Sedation or general anesthesia is not necessary. Good radiographic skills with distraction techniques are very important. It is

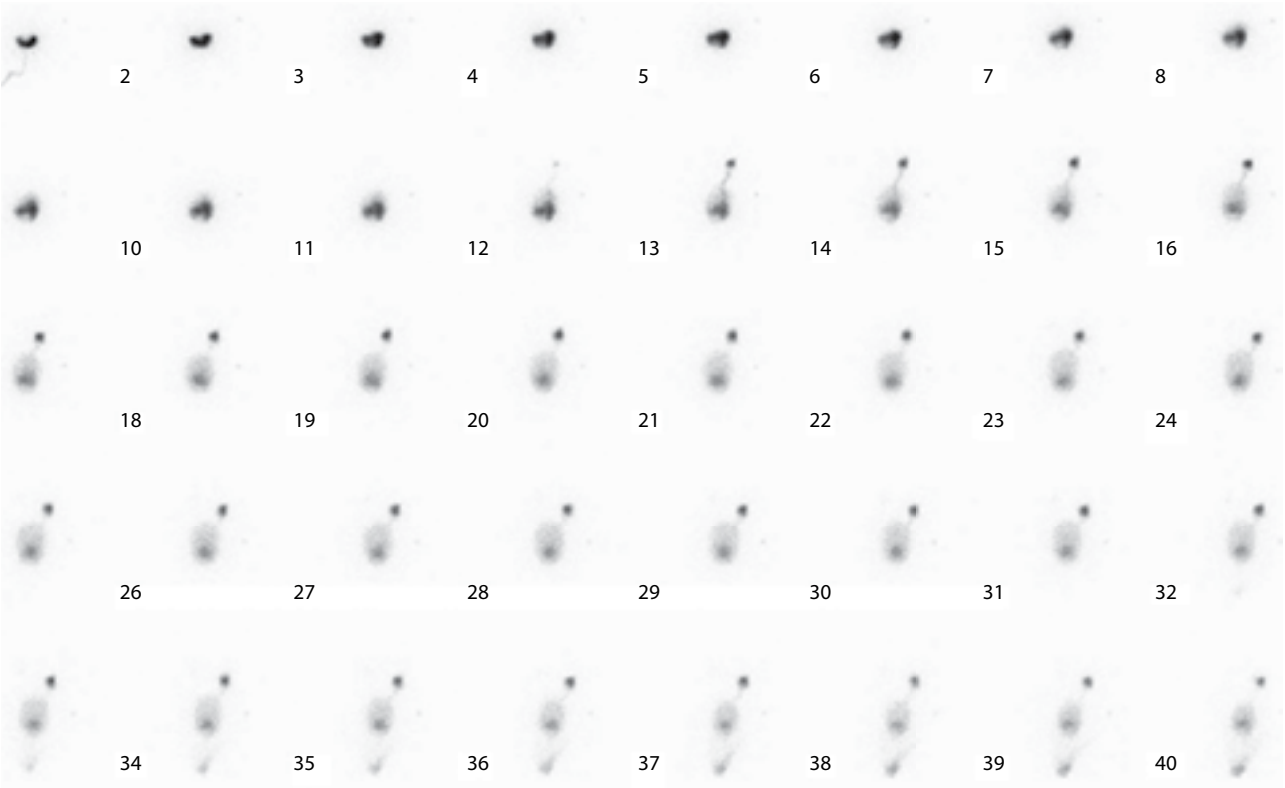

Figure 99.6 Direct isotope cystogram. Following insertion of a bladder catheter and bladder irrigation with saline, the baby feels urgency to void. Right sided vesicoureteric reflux is identified.

essential to acquire enough counts, with each image lasting, on average, between 5 and 10 minutes. A good posterior view, with a left and a right posterior oblique view, is what is needed in the vast majority of cases. The use of single photon emission computerized tomography (SPECT) is controversial. In our experience, this is almost never necessary, as we usually acquire high-quality static views, which are very informative. It is important to be aware of some normal variants: the pear-shaped kidney, the splenic impression on the lateral margin of the left kidney, the persistent fetal lobulation, and the upper or lower pole appearing hypoactive while in fact just thin. It is essential to combine the functional information gained with a DMSA scan with anatomical details, usually obtained with a US. Focal defects on DMSA are nonspecific and can be due to a wide range of conditions, including cysts, scars, calculi, tumors, foci of dysplasia, congenital abnormalities, and infarcts following arterial or venous thrombosis or congenital vascular anomalies.

In the context of urinary tract infections, an *early* DMSA scan, performed within 2–3 weeks from the infection, will inform on parenchymal inflammatory/infective involvement, which may or may not lead to permanent renal scars. A repeat DMSA scan 4–6 months after the latest infection will be able to show the presence of scars. If the clinical question is related to the presence of renal scars, then a DMSA should be done 4–6 months after the infection.

Dynamic radionuclide renography

PATIENT'S PREPARATION

The child should be appropriately hydrated. This allows normal flow of urine throughout the renal parenchyma and pelvicalyceal system. If the child is suboptimally hydrated, the tracer will progress slowly through the renal parenchyma and collecting system, thus giving a false impression of obstruction. In some centers, intravenous fluids (saline 10–15 mL/kg) are given, starting 30 minutes prior to the tracer injection. In other centers, oral hydration is preferred. It is also essential that the child is immobile during the examination: this is achieved with sandbags at both sides of the neonate and Velcro straps. If the neonate has been fed prior to the start of the examination, it is likely that he/she will fall asleep and keep still. Sedation/general anesthesia is not necessary and should not be used.

EVALUATION OF THE DRF

This is achieved by drawing regions of interest (ROIs) around each kidney at a time after tracer injection when the parenchyma-to-background ratio is optimal and no significant tracer has reached the collecting system (normally between the first and the second minute after tracer injection in the case of tracers used in dynamic renography). ROIs around each kidney, to subtract background activity, are also drawn. A precise estimate of the DRF can be challenging in the neonate, with immature kidneys and

consequent reduced tracer uptake and a relatively high background activity, even more so if there is also chronic renal failure (for example, due to posterior urethral valves), because the kidneys extract the tracer with much less avidity. Another challenging clinical situation is when one of the kidneys is much bigger than the other, for example, in a neonate with prenatally diagnosed severe hydronephrosis.

In a neonate with antenatally diagnosed hydronephrosis, functional imaging is normally deferred until the child is 2 or 3 months old, with better, even if not complete, renal maturation. Occasionally, a functional study may be requested in a younger infant: the clinical question then is whether a kidney shows any significant function at all or not, leading to the consideration of a possible nephrectomy versus more conservative treatments.

EVALUATION OF DRAINAGE

Drainage can be influenced by several different factors, especially in the neonate: the function of the kidney, the hydration status, the size of the renal pelvis, the bladder status, and the effect of gravity (supine versus upright position). Therefore, an accurate evaluation of drainage has to take into account all these factors. Intravenous furosemide administration (5 mg in neonates and infants up to 6 months of age) can help to distinguish between an obstructed renal pelvis and a dilated nonobstructed one. Furosemide can be administered immediately after the radioactive tracer (F0), 15 minutes prior to tracer injection (F–15), or 20 minutes afterward (F+20). Each of these protocols causes a different diuresis during the renogram. In an attempt to avoid prolonging the renogram excessively, with likely motion artifacts as the child cannot lie still for too long, the F0 protocol is highly favored. It may happen that the neonate voids in the nappy during the dynamic renography, especially after administration of furosemide: this can be helpful as it shows the drainage pattern with an empty or almost empty bladder, and it can even demonstrate the possible presence of VUR. An image after change of position (from supine to upright) at the end of the dynamic renography is essential to differentiate an obstructed pelvis from a dilated nonobstructed one.

The use of a bladder catheter during the dynamic renography as a way of draining the bladder is controversial. This is advocated in several parts of the world, especially in North America, to eliminate the effect of a full bladder on the drainage from the upper tracts. In Europe, practitioners tend to prefer an image following change of posture and micturition. However, in the case of a neuropathic bladder, the use of a bladder catheter is strongly advised.

There are computerized methods to assess drainage. The half-time diuretic washout method calculates how long it takes to halve the counts within the renal pelvis following furosemide administration. This method is only reliable if it gives a normal value (<10 minutes half-time). If it is prolonged, it cannot differentiate between a dilated pelvis and an obstructed one, as it does not take into account the size of the renal pelvis, the bladder status, the gravity effect, and the hydration status, and therefore, in the context of antenatally diagnosed hydronephrosis, it should not be relied upon. Methods such as the pelvic outflow efficiency (PEE) or the normalized residual activity (NORA) evaluate how much tracer has left the kidney as a percentage of what has come into the kidney (PEE), or how much tracer has remained in the kidney as a percentage of the amount that has left the kidney (NORA).

INTERPRETATION OF DRAINAGE AND DEFINITION OF OBSTRUCTION

It is important to bear in mind that slow drainage via a dilated collecting system on dynamic radionuclide renography does not necessarily mean obstruction in an asymptomatic infant with antenatally diagnosed hydronephrosis. A dilated pelvis and/or ureter can be due to a number of conditions: PUJ or VUJ anomaly with obstruction, PUJ dilatation with no obstruction, VUR, megaureter with or without VUJ dysfunction, or a complex duplex system with a dilated upper moiety. All these conditions can be associated with slow drainage on the dynamic radionuclide renography. Urinary stasis within a dilated renal pelvis/ureter does not necessarily cause suffering of the renal parenchyma. Even a stenosis at the PUJ may not cause resistance to urinary outflow that is sufficient to provoke suffering of the renal parenchyma, with a consequent drop in function. Therefore, the only definition of obstruction that has been accepted at present is "resistance to urinary outflow that, left untreated, will cause deterioration of renal function." As can be seen, unfortunately, this definition is a retrospective one. Therefore, in an asymptomatic patient who has had a single dynamic renography examination, which shows slow drainage and urinary stasis either at the PUJ or at the VUJ, obstruction cannot be reliably diagnosed, as it is not known whether this condition will cause a fall in function of that kidney or not.

MRI and CT: "cross-sectional imaging"

In the presence of a transonic/anechoic lesion on US, there is no indication for cross-sectional imaging as cystic lesions can be followed with US. Solid lesions will usually require further imaging after the initial US. The major differential diagnosis of renal tumors in the neonate is that of a mesoblastic nephroma (Figure 99.7), as Wilms tumors (Figure 99.8) are rare in the neonatal period, but still recognized. Neuroblastoma (in the adrenal) can sometimes be confused with a renal mass lesion and should also be considered. MRI is the optimal technique to assess mass lesions as it does not use radiation and has far superior inherent tissue contrast resolution compared to CT and can therefore differentiate between tissue types even if they are a similar level of density (perceived as similar "greyness") on CT. CT has good spatial resolution and is fast to acquire but carries a heavy radiation dose penalty. Furthermore, the neonate has little fat to provide contrast between adjacent structures, and CT cannot differentiate between tissues of similar density even though they may be of very different tissue types or indeed pathological. MRI can also

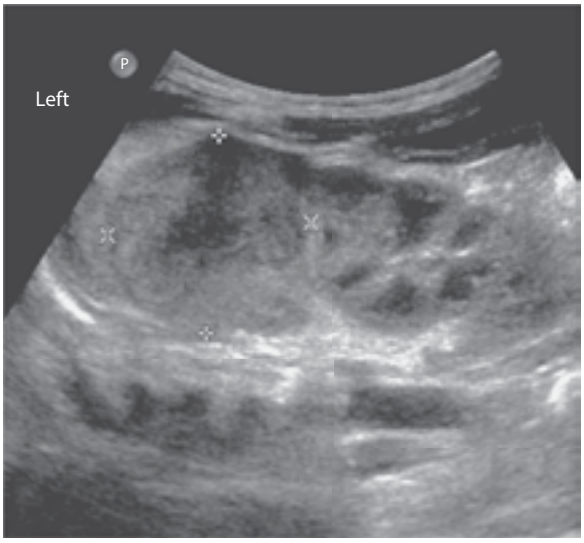
provide exquisite depiction of the urinary tract, especially if it is dilated, as specific sequences will show water, and hence urine-containing structures, in great detail. This examination is also termed magnetic resonance urography (MRU) (Figure 99.9). It is therefore increasingly useful in supplementing the information obtained by US regarding dilatation, anatomy, and in some cases, the function of the renal tract.

The use of MRI in the neonatal age group was previously limited by the length of time to acquire various sequences (up to 10 minutes each) and, therefore, the risk of patient movement degrading the images, but the sequences are now much faster, and techniques are available to counteract the effects of breathing and cardiac movement. MRI can be performed under general anesthetic if the feed-and-wrap technique fails.

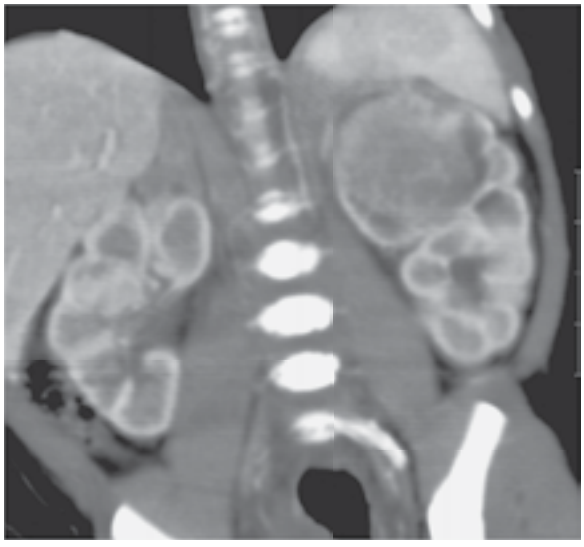
SPECIFIC CONDITIONS IN THE NEONATAL PERIOD

Hydronephrosis

Hydronephrosis in the neonatal period is most commonly imaged subsequent to an antenatal diagnosis of renal pelvic dilatation being made at a routine antenatal US scan. It is important to clarify if the dilatation is bilateral and



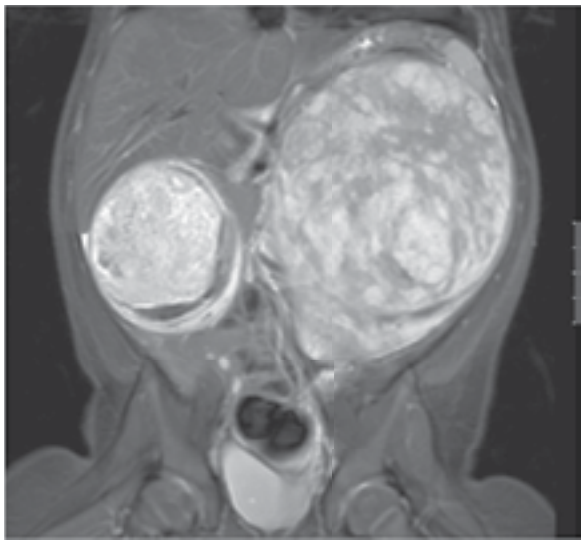
(a)



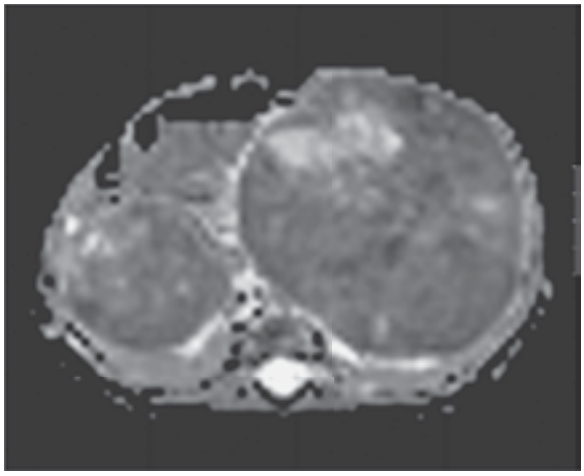
(b)

(c)

Figure 99.7 Mesoblastic nephroma in a 6-day-old male patient. **(a)** Ultrasound shows a mass at the upper pole of the left kidney. **(b)** CT scan in the same patient showing the left upper pole mass but poorly differentiating between the renal parenchyma and the collecting system. **(c)** Magnetic resonance image with T2 weighting showing the displacement of the collecting system around the mass and demonstrating the normal corticomedullary differentiation in the rest of the left kidney and in the right kidney.



(a)



(b)

Figure 99.8 MRI in 3-month old with bilateral Wilms tumors. **(a)** Short tau inversion recovery (STIR) sequence in coronal plane showing the marked distortion of the normal anatomy due to the bulk of the tumors. **(b)** Apparent diffusion coefficient (ADC) sequence showing extensive areas of low signal (dark grey) within the tumors, which represent densely packed tumor cells. The area of high signal (white) anteriorly in the larger left-sided tumor indicates an area of necrosis.

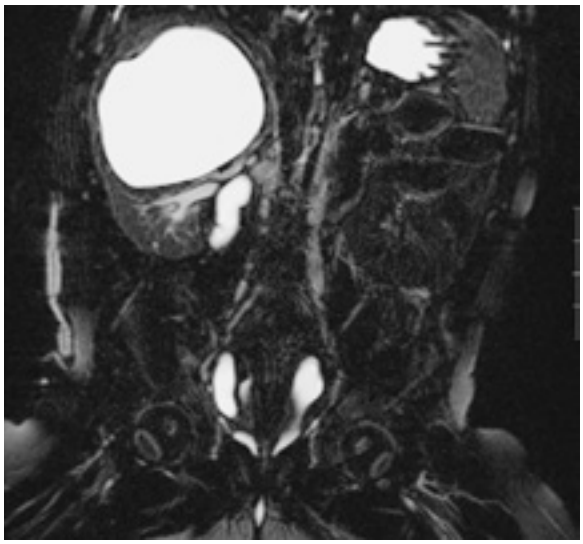


Figure 99.9 MRI in a 6-month-old female patient in whom ultrasound had been unable to differentiate between a right-sided pelviureteric junction obstruction and a dilated moiety of a duplex kidney. This heavily T2-weighted sequence shows that the right kidney is in fact duplex with a very dilated upper moiety and a small and compressed lower moiety. Incidental note was also made of a didelphus uterus in the pelvis.

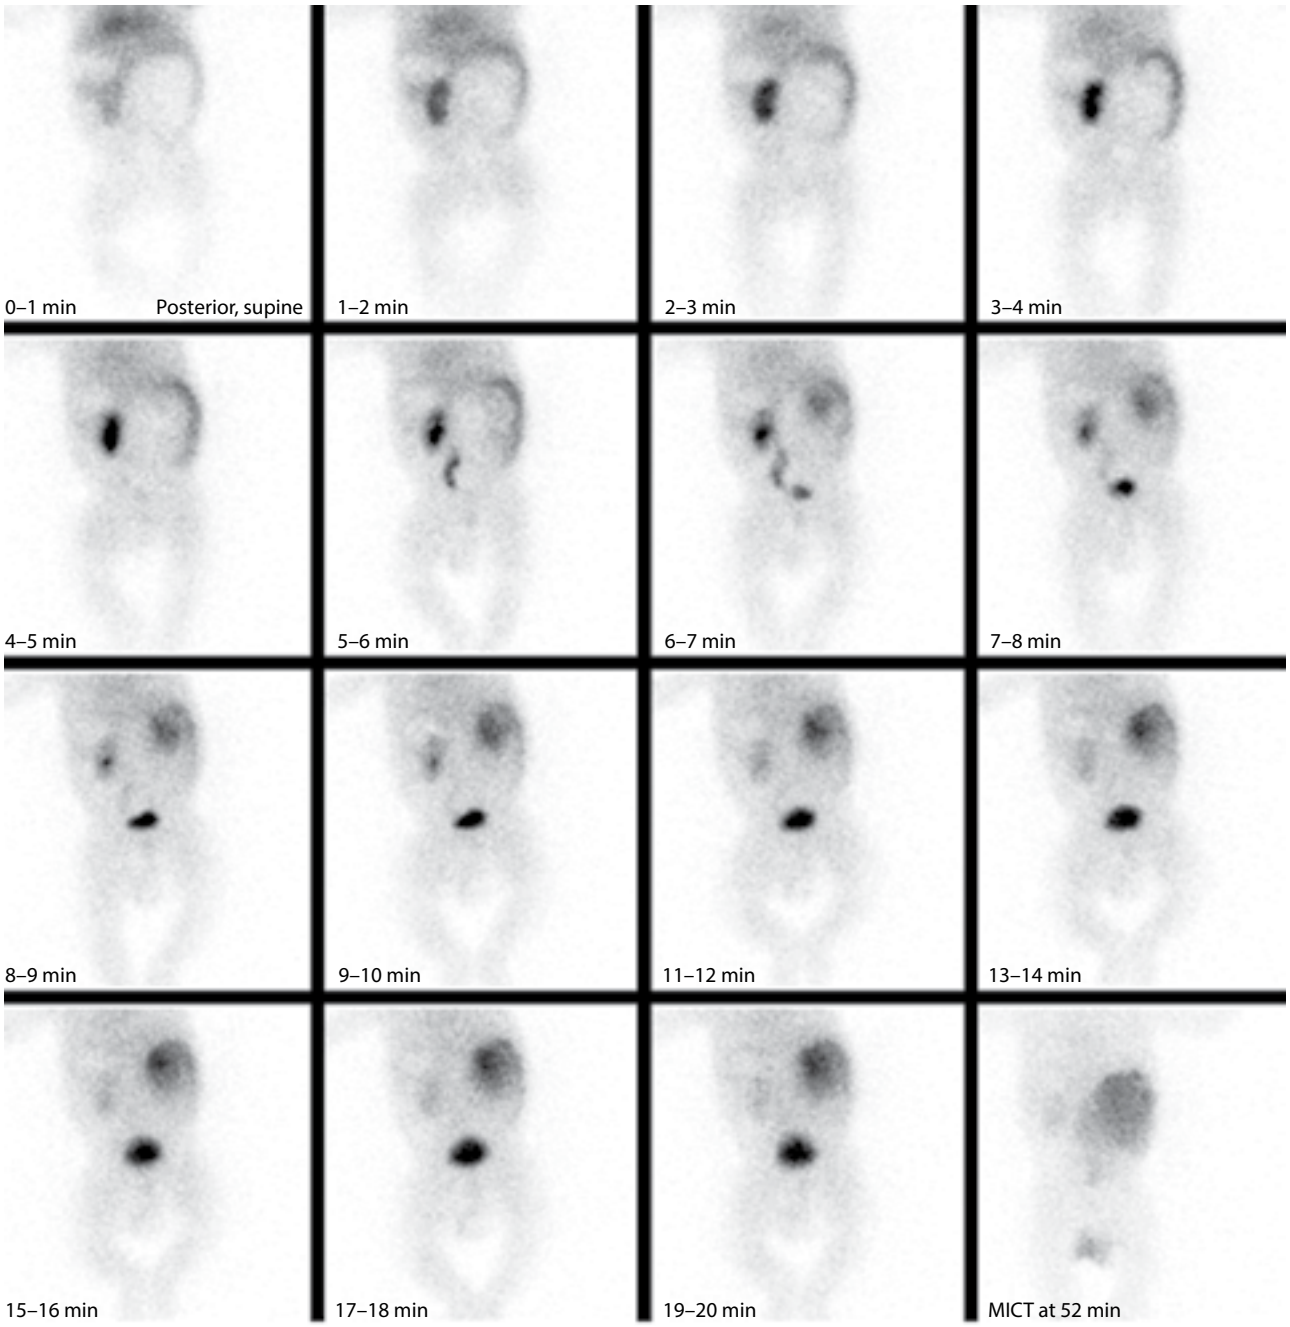
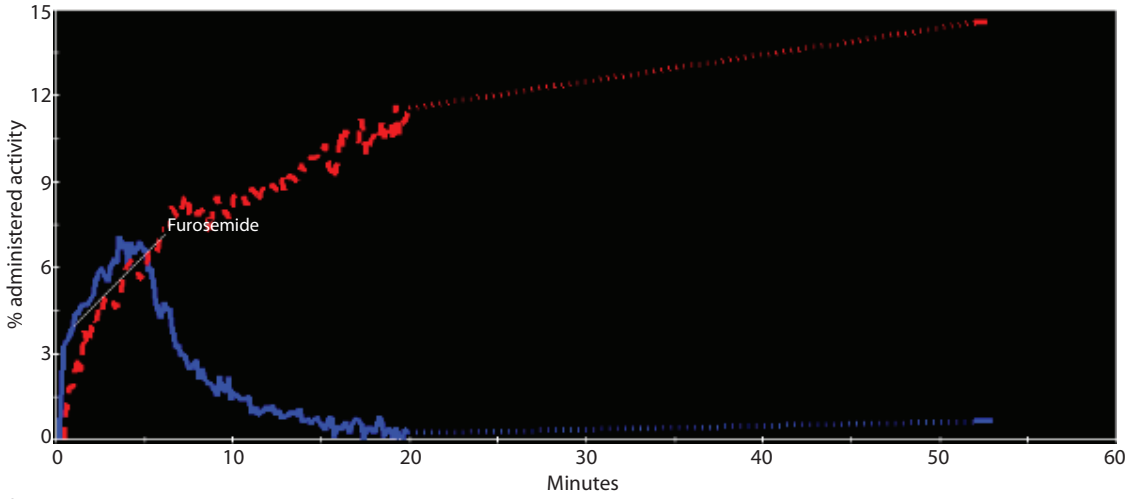
how dilated the renal pelvis is. Imaging will always be by US. Bilateral pelvic dilatation (>7 mm) necessitates close inspection of the bladder (for bladder wall thickening and ureteroceles) and, in boys, will prompt MCUG to exclude posterior urethral valves. A unilateral antenatal hydronephrosis requires functional evaluation, normally with a MAG3 renography, to assess the split function of the hydronephrotic kidney and its drainage. It is important to realize that slow drainage does not necessarily mean obstruction. Follow-up of a hydronephrotic kidney is normally performed with US. Significant increase in renal pelvis dilatation on US will prompt a repeat functional study. A very significant unilateral dilatation at diagnosis may indicate an intrinsic severe PUJ obstruction, and a functional study (often with MAG3, but also DMSA can be used—especially if the kidney is much enlarged with a very stretched renal parenchyma) will be indicated to establish if the affected kidney has any useful function. Occasionally, a PUJ anomaly may be associated with a VUJ anomaly; the MAG3 renogram may find it difficult to identify both conditions (Figure 99.10), and it is essential to interpret the findings of the isotope study in comparison with a contemporaneous US. A very enlarged and stretched kidney may still recover its function if prompt intervention is instigated. In the follow-up of an antenatally diagnosed hydronephrosis with radionuclide renography, a change in DRF of <5% is not significant. Changes between 5% and 10% have to be evaluated in context. If the child is younger than 6 months of age at the time of the first renogram (with consequent renal immaturity and poor tracer uptake on the renogram, and raised background activity) and the renal parenchyma is very stretched around a dilated renal pelvis, then the estimated value of split renal function will not be very precise. A follow-up renogram when the child is older and the kidneys are more mature, with better tracer uptake and less background activity, may show a change in split renal function between 5% and 10% in comparison to the baseline renogram but no significant change in the true function of that kidney.

A megaureter can be associated with obstruction at the distal end of the ureter and/or VUR, or may be nonobstructed and nonrefluxing. The first evaluation is with US,

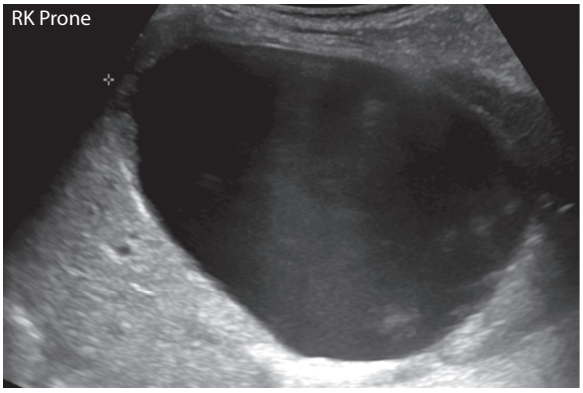


(a)

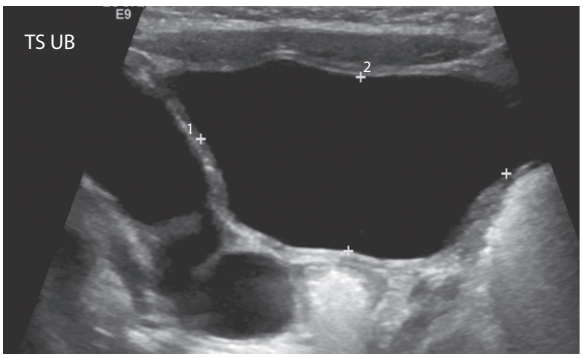
Figure 99.10 **(a)** MAG3 renogram of a 6-week-old male infant with an antenatally diagnosed gross right hydronephrosis. The isotope study shows a grossly enlarged right kidney with a parenchyma severely stretched around a massively dilated collecting system, with a right renal pelvis measuring 6 cm in maximum diameter on ultrasound. Urinary stasis is seen at the level of the right PUJ, but no significant stasis is seen in the right ureter. (*Continued*)



(b)



(c)



(d)

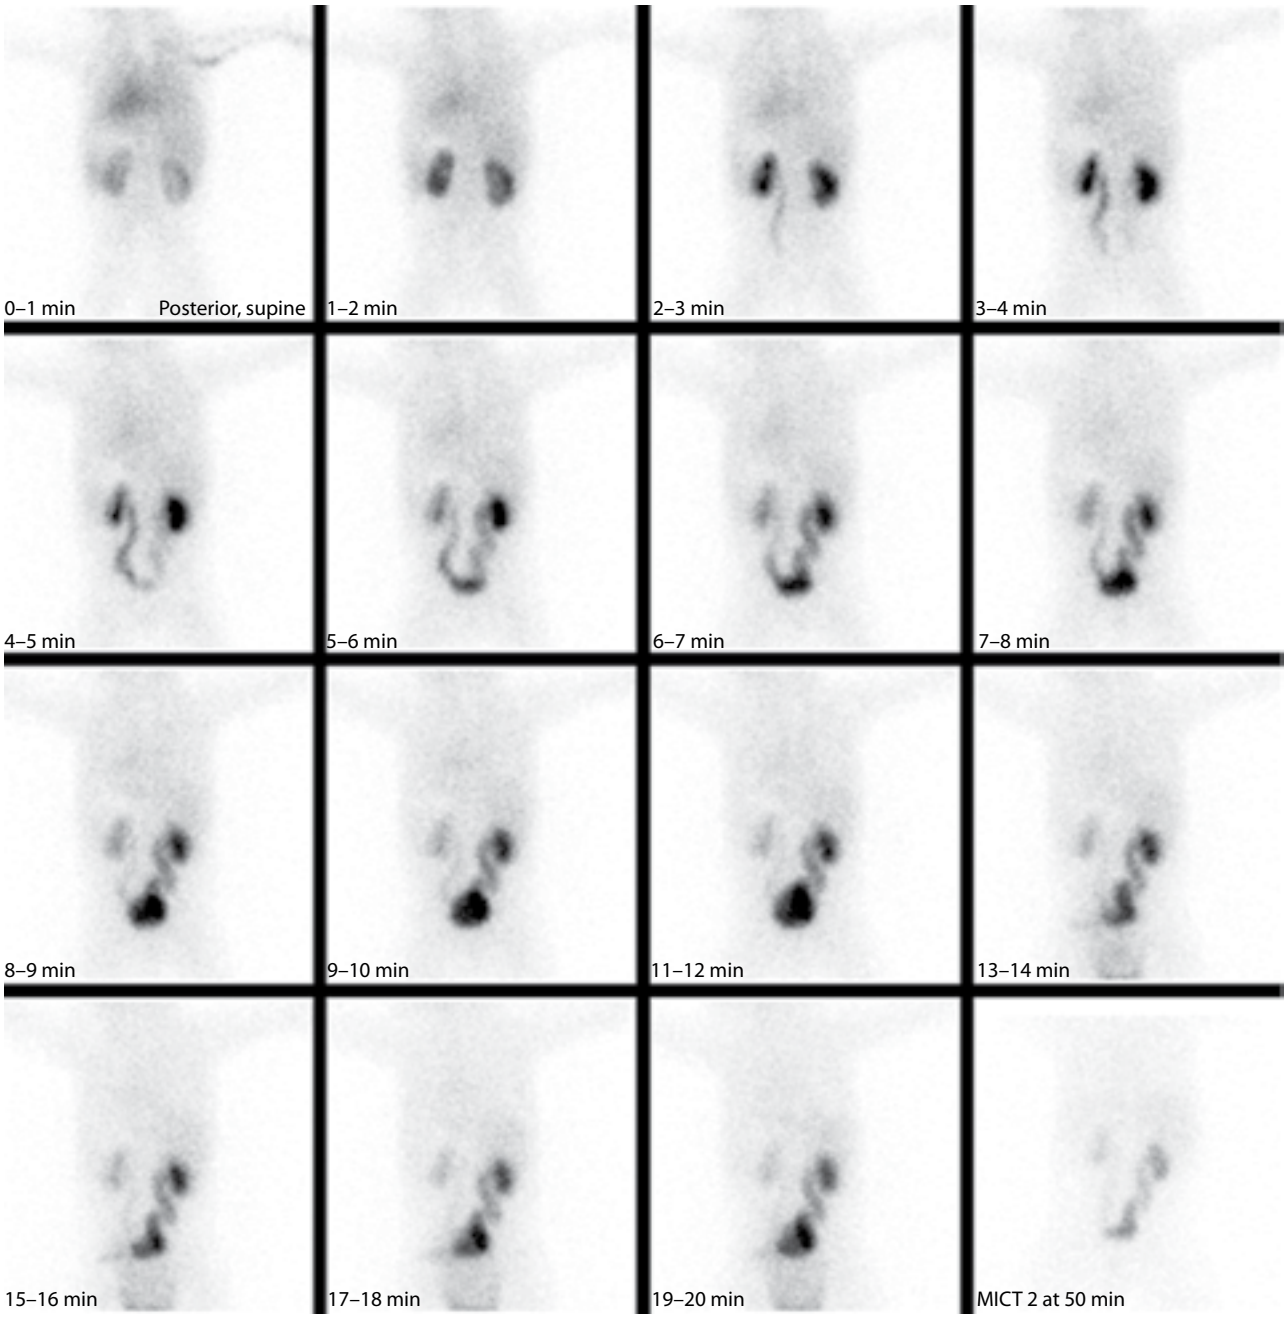
Figure 99.10 (Continued) **(b)** There is very slow drainage from the right renal pelvis as demonstrated in the drainage curve. **(c)** The ultrasound also shows marked dilatation of the renal pelvis, and these appearances combined are compatible with a right PUJ anomaly. **(d)** However, the ultrasound also shows a significantly dilated right ureter, measuring 14 mm in calibre at the distal end. Therefore, a concurrent right VUJ anomaly is also suspected. Cystoscopy confirmed a tight VUJ stenosis, which underwent balloon dilatation. A retrograde contrast study showed also a narrow right PUJ. This was corrected with a right pyeloplasty. This case highlights that a right VUJ anomaly may be missed on isotope dynamic renography, and it is essential to interpret the findings of the isotope study in comparison with a contemporaneous ultrasound.

which will show the calibre of the ureter at the proximal and at the distal ends, as well as the size of the renal pelvis. Functional imaging, often in the form of a MAG3 diuretic renography, will show the parenchymal function of the affected kidney and the level of urinary stasis (renal pelvis or ureter and where in the ureter) (Figure 99.11). It is important to realize that the radionuclide dynamic renography may fail to show significant ureteric stasis and therefore be falsely negative (Figure 99.10).

"Bright" kidneys

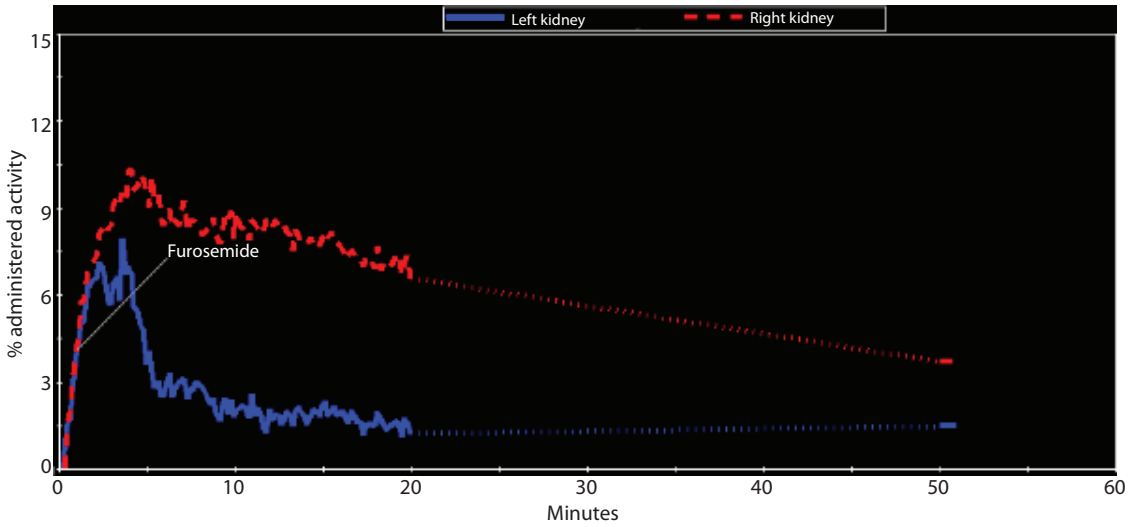
In an unwell neonate, US may be requested to obtain a baseline and to exclude any related renal cause for the infant's condition. On these occasions, the observation of "bright" kidneys may sometimes be made. "Bright" in this context implies that the parenchyma (both cortex and medulla) is significantly more echo bright (i.e., hyperechoic) than the parenchyma of the adjacent liver or spleen. The kidneys may also be small, normal-sized, or large depending on the underlying cause (Figures 99.2 and 99.3). (Normal neonatal kidneys may be slightly more echogenic than the adjacent liver or spleen but not markedly so.)

The differential diagnosis of enlarged hyperechoic kidneys in the neonate includes acute tubular necrosis, renal vein thrombosis, polycystic kidney disease (autosomal dominant or autosomal recessive), autosomal dominant glomerulocystic kidneys, dysplastic kidneys (with or without an associated syndrome) (Figures 99.12a and 99.13), and rarely, an underlying metabolic disorder (Figure 99.2). In the case of renal vein thrombosis, a functional study (often DMSA) can be useful once the acute episode has resolved to assess if the kidney drained by the thrombosed vein has lost

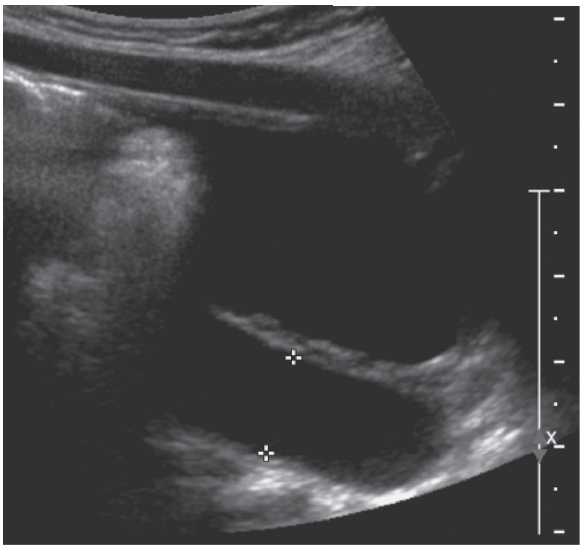


(a)

Figure 99. 11 **(a)** MAG3 renogram of a 4-month-old male infant with bilateral hydroureteronephrosis, presenting with urinary tract infection. Both kidneys function equally and normally. (*Continued*)



(b)



(c)

Figure 99. 11 (Continued) **(b)** The left kidney drains well via a mildly dilated ureter (5 mm on ultrasound). The right kidney shows slower drainage with significant urinary stasis in the lower third of the right ureter, even following change of posture and micturition. The ultrasound shows an 8 mm right renal pelvis. **(c)** The right ureter is dilated distally, measuring 12 mm. The imaging appearances raise the probability of a right VUJ anomaly. The baby underwent cystoscopy, which showed a tight right VUJ. This was dilated with a balloon, and a right JJ stent was placed.

significant function (Figure 99.14). A functional study may also be clinically helpful in the case of an arterial thrombosis (Figure 99.15).

Cystic kidneys

These will usually present in the neonate because the infant is in renal failure, because bilateral mass lesions can be felt in the flanks, or because the patient has a US scan for another reason. The main groups of cystic disease are listed in a previous section, "Bright Kidneys." A multicystic dysplastic kidney (MCDK) may be diagnosed antenatally but may be picked up in the neonatal period or later (Figure 99.16). Tuberous sclerosis may also give rise to multiple cysts in the kidneys, but it would be unusual for this to present in the neonatal period (Figures 99.13 and 99.17). US will always be the first examination, and usually, no other imaging would be necessary at the neonatal stage. Functional imaging may be performed later. In the case of an MCDK, functional imaging will confirm that the kidney is nonfunctional and will look for the possible presence of slow drainage in the contralateral kidney due to ureteropelvic junction anomaly. Care must be taken not to misinterpret marked hydrophosis as an MCDK and vice versa. Differentiation is usually possible by demonstrating that the "cysts" connect to the renal pelvis and are therefore in fact dilated calyces.

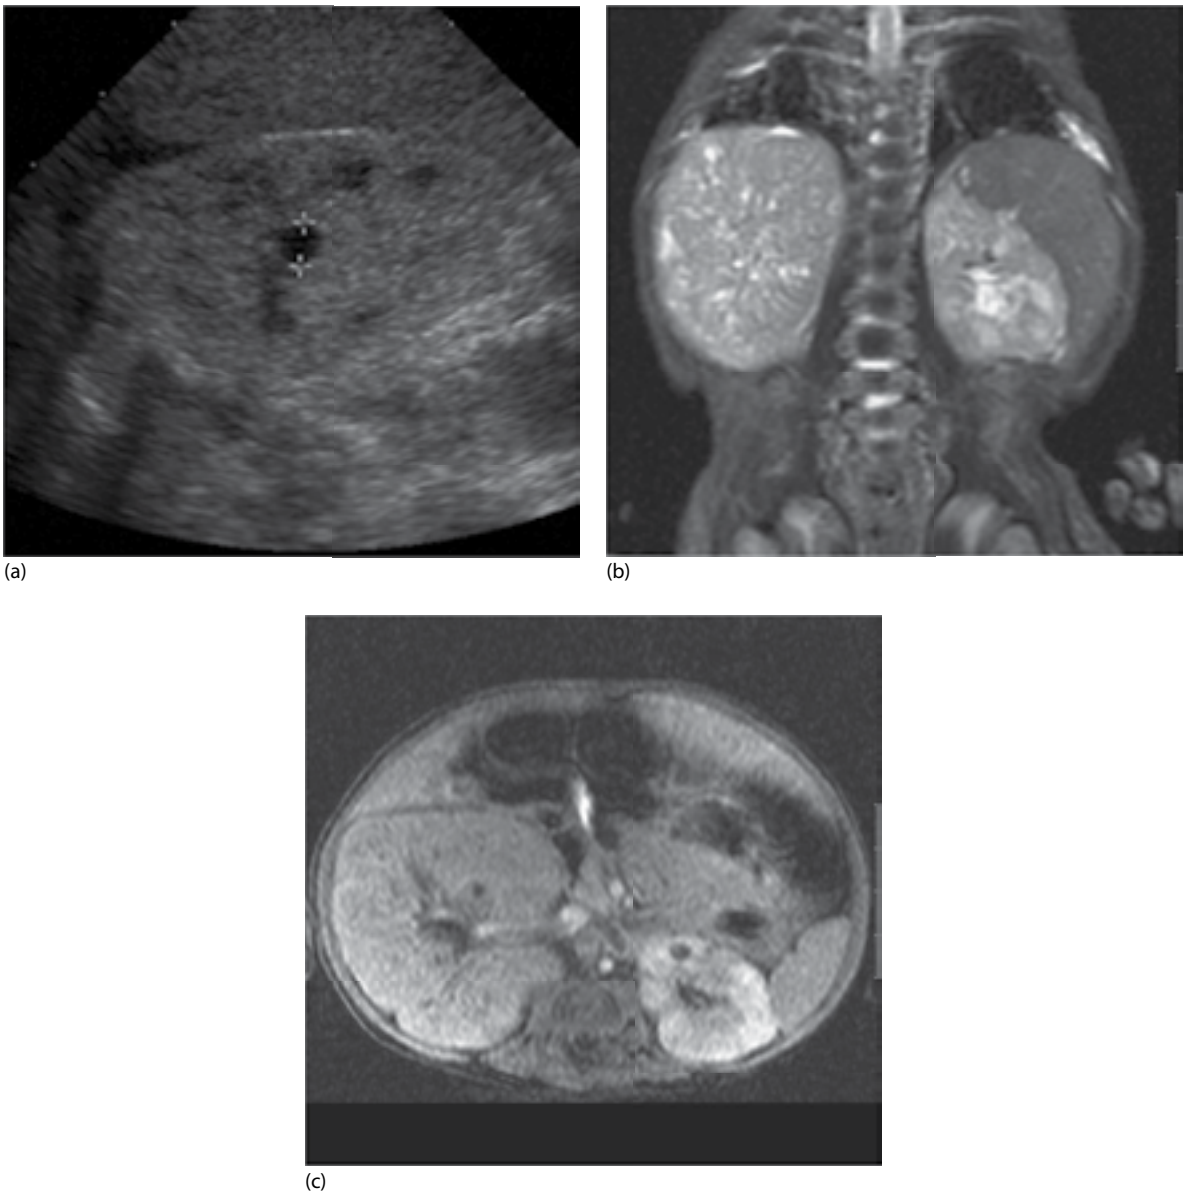


Figure 99.12 **(a)** Ultrasound in a 1-month-old patient with dysplastic kidneys. Note the small cysts in an otherwise featureless parenchyma. **(b)** MRI in the same patient at the same time. This coronal STIR sequence shows the enlargement of the kidneys and the very abnormal renal architecture, with a typical striated appearance. **(c)** Axial T1-weighted sequence following gadolinium demonstrating the small cysts seen on ultrasound and poor enhancement.

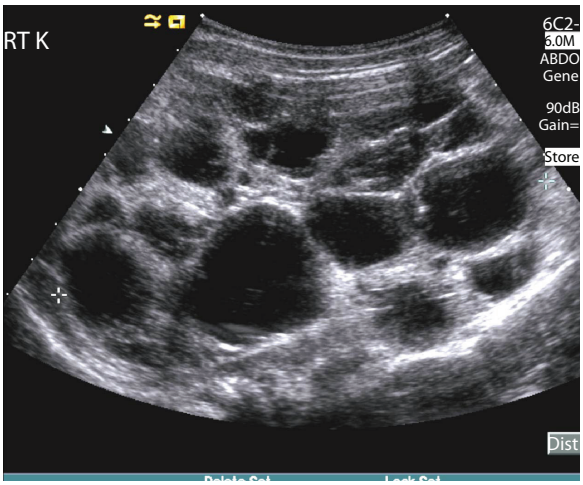
Tumors

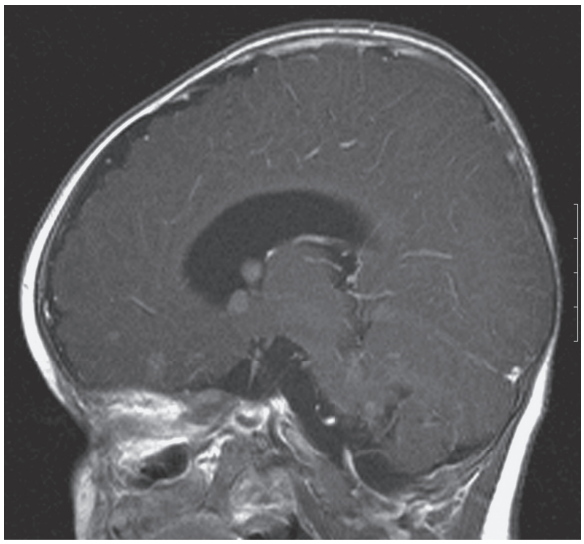
Renal tumors in the neonatal period are rare, but the most likely type would be a mesoblastic nephroma. On US, this mass lesion would generally be mainly solid, if not entirely so. Usually, no further imaging is required, and surgery in the neonatal period is curative. Occasionally, the surgeon may wish for further cross-sectional imaging before operating, and in this instance, MRI would be the modality of choice if it is available. There is no indication for functional imaging for the affected side, but functional imaging may be indicated to assess the function of the contralateral kidney before surgery.

Renal anomalies

Duplex kidneys (Figure 99.18a), cross-fused ectopic kidneys (Figure 99.18b), horseshoe kidneys, and other anomalies are usually first detected by US. US will also be used for monitoring and for searching for other related anomalies, for example, spinal anomalies in patients with the VATER (Vertebral anomalies, Anal atresia, Tracheo-esophageal fistula and/or Esophageal atresia, Renal and radial anomalies) spectrum (Figure 99.18c). Functional imaging is essential as it informs on the function of the upper and the lower moieties of the duplex kidney and on the drainage (Figure 99.19). Occasionally, it can inform also on the presence of VUR



(a)



(b)

Figure 99.13 **(a)** Ultrasound in a 2-month old with large palpable kidneys showing multiple cysts. The differential is between autosomal dominant polycystic kidney disease and tuberous sclerosis. **(b)** Brain MRI in the same patient confirms the presence of tubers (shown adjacent to the lateral ventricle) and thus confirms the diagnosis of tuberous sclerosis.

Figure 99.14 DMSA scan in a 5-month-old extremely prematurely born male infant, with a recent history of a right renal vein thrombosis. The right kidney is nonfunctional. The left kidney is damaged with focal abnormalities in the mid-upper pole laterally and at the lower pole. The ultrasound showed very dampened arterial flow to the right kidney and no detectable venous drainage.

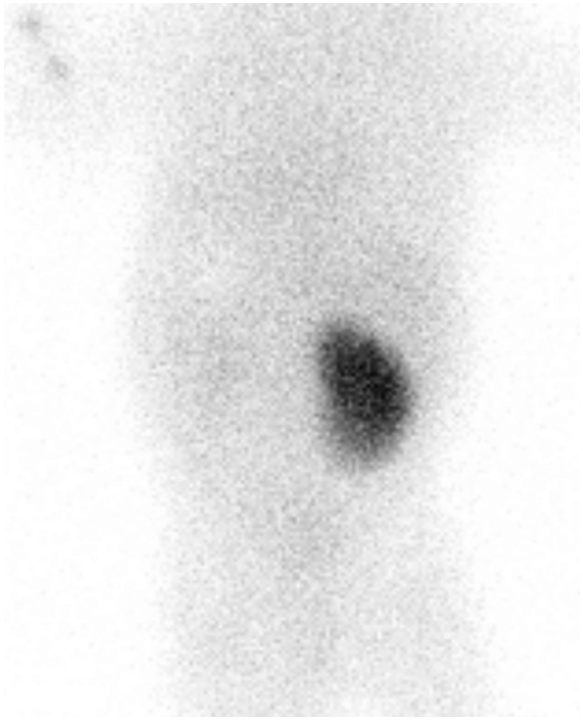


Figure 99.15 DMSA scan in a 20-day-old baby boy with extensive cerebral infarcts and significantly reduced arterial flow in the left kidney on Doppler ultrasound indicative of severe left renal artery stenosis. The left kidney is nonfunctional; the right kidney is normal.

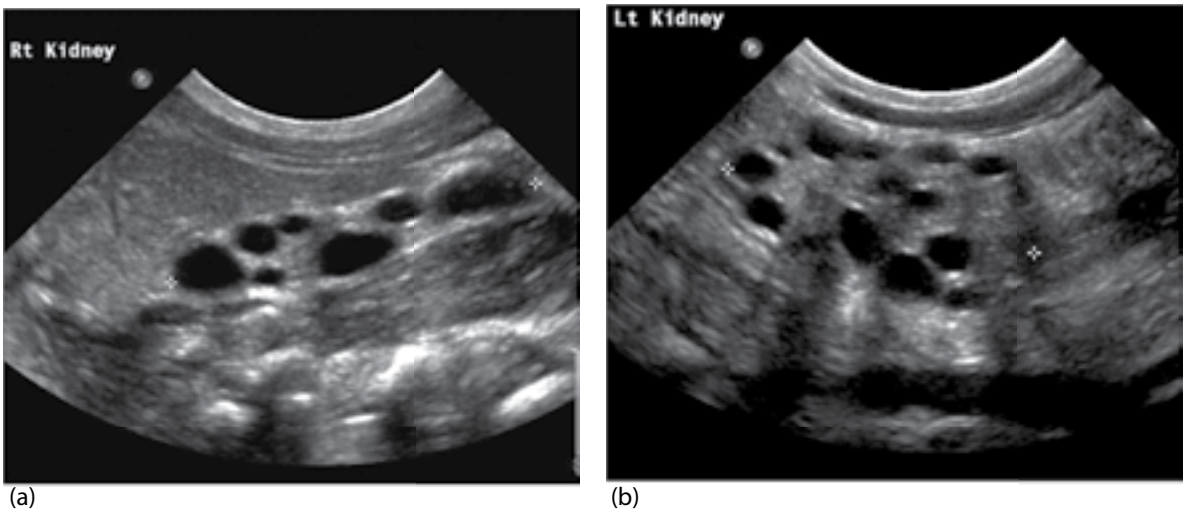

(a) (b)

Figure 99.16 Ultrasound showing a right multicystic dysplastic kidney in a newborn patient. There are multiple non-communicating cysts in the renal parenchyma of the right kidney **(a, b)**. The cysts may vary in size but are usually seen throughout the kidney(s), and the intervening parenchyma is echo-bright. A true MCDK has no function on DMSA.

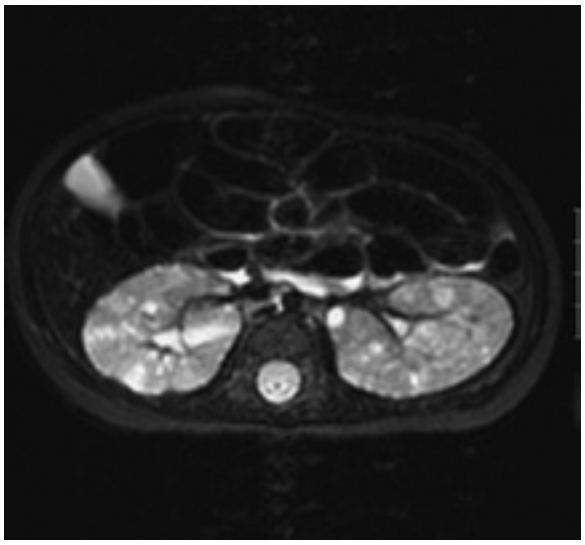

Figure 99.17 MRI in a 5-month old with tuberous sclerosis. This axial STIR sequence shows multiple cysts in both kidneys. These are easily demonstrated by ultrasound, but MRI is also performed to exclude liver or pancreatic involvement.

(Figure 99.20). MRI may be very useful in the most complicated cases, being able to demonstrate the whole of the urinary tract in any desired plane and giving some information about function and drainage. Unless there are specific complications requiring further intervention, all of the secondary imaging may be delayed till the patient is older.

Infection

Infection in the neonatal period may be acquired at the time of delivery, be secondary to an underlying urinary tract anomaly, or be a result of instrumentation/catheter placement. If imaging were required, then US would be the first modality. If the urinary tract is anatomically normal, US may not demonstrate any abnormal findings; however, echogenic debris may be seen throughout the urinary tract. If the upper tracts are involved (pyelonephritis), it may be possible to demonstrate focal areas of low echogenicity, or the kidneys may simply be enlarged. If the patient has been systemically ill (e.g., requiring intravenous antibiotics as an inpatient), the microorganism isolated is unusual (*Klebsiella*, *Pseudomonas*, *Enterococcus*), or the child has recurrent infections, functional imaging is indicated. If the clinical question is to confirm whether the child has an acute pyelonephritis with renal parenchymal inflammatory involvement and how much of the renal parenchyma has been involved, then a DMSA performed during the infection will answer the question. If the question is whether the infant has developed renal scarring as a consequence of the infection, then a DMSA scan will have to be performed between 4 and 6 months after the infection.

Renal calculi and nephrocalcinosis

Calculi are rare in the neonatal period, but nephrocalcinosis may be seen in patients with an inherited underlying metabolic abnormality such as primary hyperoxaluria (Figure 99.2). It is most commonly asymptomatic. Nephrocalcinosis is well demonstrated on US and is described as medullary, cortical, or parenchymal. Initially, there is a mild increase in echogenicity and ringing of the pyramids, which may eventually progress to filling-in of the medullae with acoustic shadowing.

Other causes of focal echogenicity mimicking nephrocalcinosis in the neonatal period include the use of furosemide (calcification seen at the tips of the pyramids, sometimes associated with stone formation) and Tamm–Horsfall

Figure 99.19 **(a)** MAG3 renogram of a 6-week-old female infant with a prenatal diagnosis of a right duplex kidney. This confirms a right duplex kidney with a nonfunctional upper moiety and reduced function in the lower moiety. The right kidney contributes 23% to total renal function (left kidney 77%). **(b)** US demonstrates dilatation of the upper moiety **(i)** and a tortuous dilated ureter **(ii)**. There is a photopenic indentation in the right side of the bladder **(a)**, in keeping with a large ureterocele as shown on US **(iii)**.

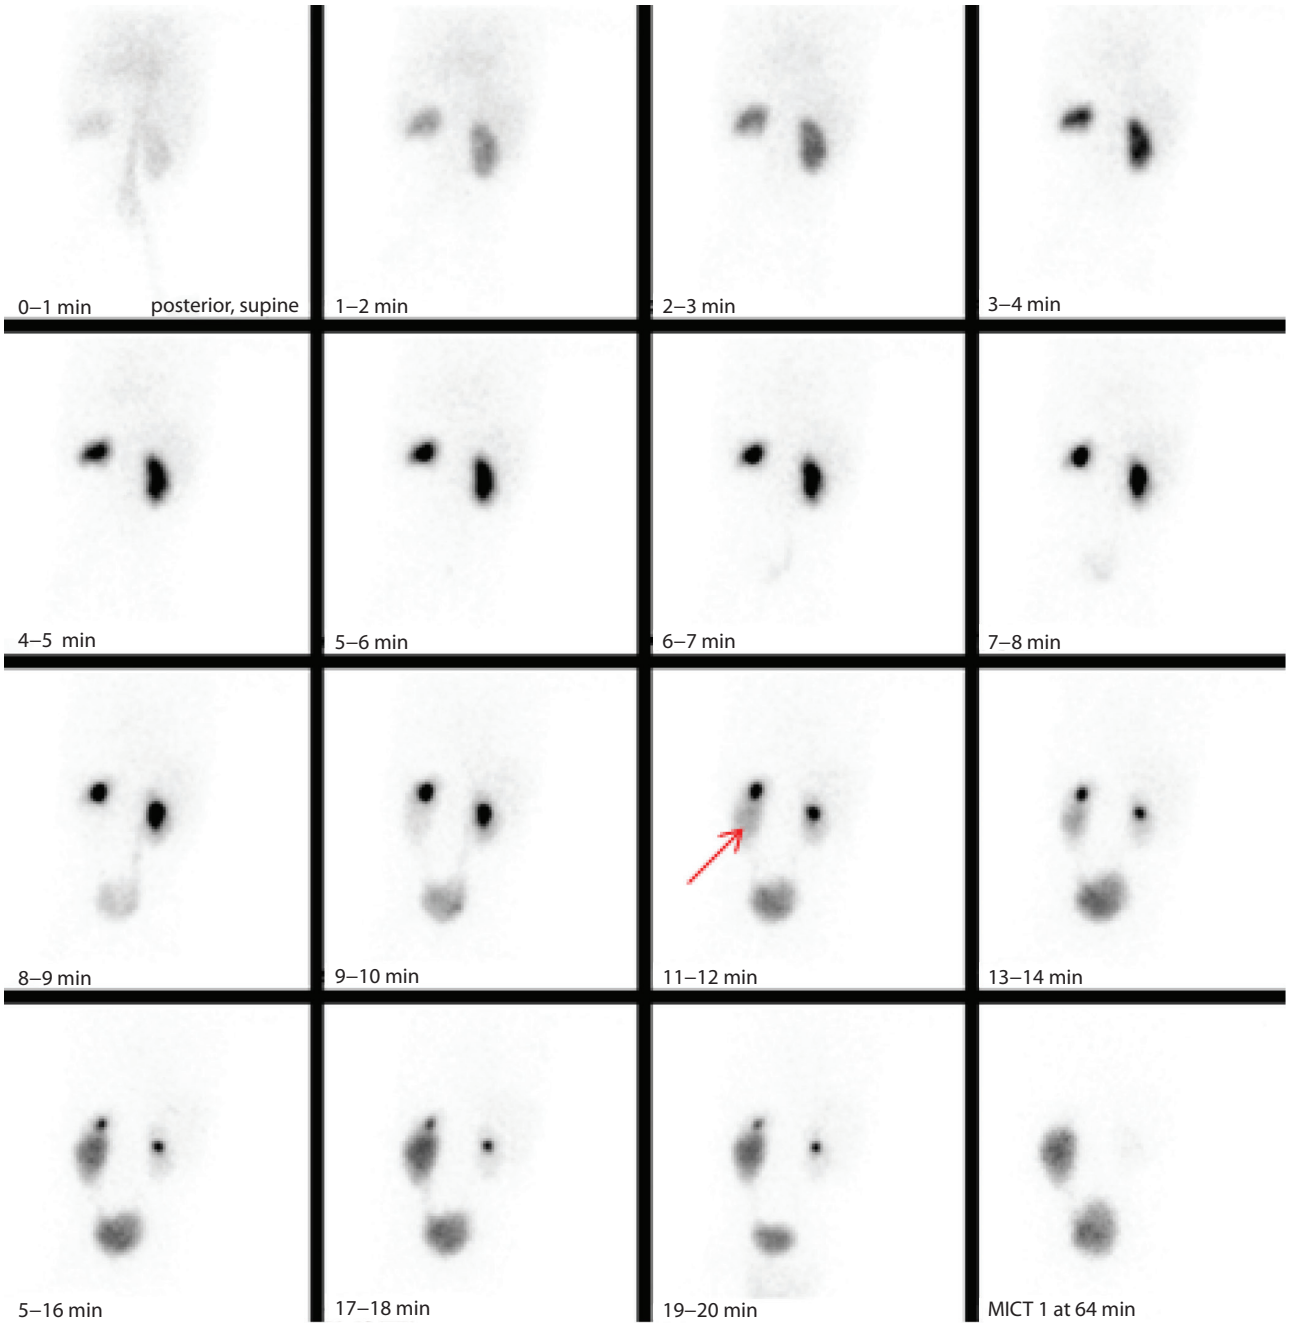

Figure 99.20 Eight-month-old baby with a left-sided duplex renal collecting system. The left lower moiety is nonfunctional. The left upper moiety shows good function. There is a clear vesicoureteric reflux in the left lower moiety during the dynamic renography, in coincidence with micturition. The right kidney is normal.

protein deposition in the medullae (which is a transitory event related to fluid regulation around the time of birth).

CONCLUSION

The US examination should always be the first imaging examination in the neonate. This may be supplemented by functional studies (DMSA or MAG3) or further anatomical studies (including MCUG and MRI [or CT]) as determined by the underlying findings on US.

Management of antenatal hydronephrosis

JACK S. ELDER

INTRODUCTION

An abnormality involving the genitourinary tract is detected in 1 in 50 to 1 in 100 pregnancies, depending on the sonographic criteria. The goal of management is to recognize and treat congenital anomalies that may adversely affect renal function or cause urinary tract infection (UTI) or sepsis. Many structural abnormalities of the urinary tract are characterized by hydronephrosis, which frequently is assumed to be obstructive. However, often antenatal hydronephrosis (ANH) results from non-obstructive causes, including vesicoureteral reflux (VUR), multicystic dysplastic kidney, and certain abnormalities of the ureteropelvic and ureterovesical junction.

DEVELOPMENT OF THE KIDNEY AND RENAL FUNCTION

The kidney is derived from the ureteral bud and the metanephric blastema. During the fifth week of gestation, the ureteral bud arises from the mesonephric (Wolffian) duct and penetrates the metanephric blastema, which is an area of undifferentiated mesenchyme on the nephrogenic ridge. The ureteral bud undergoes a series of approximately 15 generations of divisions, and by 20 weeks' gestation forms the entire collecting system, that is, the ureter, renal pelvis, calyces, papillary ducts, and collecting tubules. Under the inductive influence of the ureteral bud, nephron differentiation begins during the seventh week of gestation. By 20 weeks' gestation, when the collecting system is completely developed, approximately one-third of the nephrons are present. Nephrogenesis continues at a nearly exponential rate and is complete at 36 weeks' gestation. Throughout gestation, the placenta functions as the fetal hemodialyzer, and the fetal kidneys play a minor role in the maintenance of fetal salt and water homeostasis. Formation of urine begins between the fifth and ninth weeks of gestation.

The rate of urine production increases throughout gestation, and at term, volumes have been reported to be 51 mL/h.[1] The glomerular filtration rate (GFR) has been measured at 6 mL/min/1.73 m^2 at 28 weeks' gestation, increasing to 25 mL/min/1.73 m^2 at term, and thereafter triples by 3 months of age.[2] The main factors responsible for this increase in GFR after birth include an increase in the capillary surface area available for filtration, changes in intrarenal vascular resistance, and redistribution of renal blood flow to the cortical nephrons, which are much more numerous than the medullary nephrons. A congenital obstructive lesion of the urinary tract may have a deleterious effect on renal function. Severe early obstructive uropathy disrupts nephrogenesis and results in renal dysplasia.

THE FETUS WITH ANH

When a fetus is identified with a suspected urinary tract abnormality, the goals of management include determining the differential diagnosis, assessing the associated anomalies, and determining the fetal and postnatal risk of the anomaly. Hydronephrosis is recognized by demonstrating a dilated renal pelvis and calyces. The ureter and bladder may be dilated also. The likelihood of having a significant urinary tract abnormality is directly proportional to the severity of hydronephrosis.[3,4] If the renal pelvic diameter is more than 2 cm, 94% have a significant abnormality of the urinary tract requiring surgery or long-term urologic follow-up. If the fetal renal pelvic diameter is between 1.0 and 1.5 cm, 50% have an abnormality, and if the dilated renal pelvis is less than 1 cm, only 3% have a significant abnormality.[5] A renal pelvic diameter of at least 4 mm before 27 weeks' gestation and at least 7 mm after 27 weeks' gestation has been considered significant.[6] The later the sonogram is performed, the more likely an existing abnormality will be detected, because the obstructed renal pelvis gradually enlarges throughout gestation. In addition, in utero, the fetus is usually upside down in the uterus and urine is draining uphill. For example, Fugelseth et al.[7] reported that only one-third of a series of women carrying babies with

a urologic anomaly had an abnormal ultrasound study at 15–21 weeks' gestation.

The differential diagnosis of ANH is provided in Table 100.1. Virtually all of these conditions can cause bilateral hydronephrosis. A distended bladder and bilateral hydronephrosis is suggestive of bladder outlet obstruction, such as posterior urethral valves (PUVs) or a large ectopic ureterocele obstructing the bladder neck, but fetuses with non-obstructive conditions, such as high-grade VUR or prune belly syndrome, also may have bilateral hydroureteronephrosis and a distended bladder. In fetuses with a urologic anomaly, associated abnormalities are common. For example, in one series of fetuses with bilateral hydronephrosis and oligohydramnios, 16 of 31 (55%) had an associated structural or chromosomal abnormality.[8] Congenital heart disease and neurologic deformities can often be detected, if they are present. In contrast, large bowel abnormalities, such as imperforate anus, are more difficult to detect by prenatal sonography, whereas recognition of small bowel anomalies, such as atresia, are usually straightforward.

The main considerations in determining fetal management include overall fetal well-being, gestational age, whether the hydronephrosis is unilateral or bilateral, and the volume of amniotic fluid. Until recently, there were no guidelines for determining how frequently to image the fetus or whether specific intervention was necessary. If hydronephrosis is unilateral, usually no specific fetal therapy is necessary. For example, if the hydronephrosis is secondary to a ureteropelvic junction (UPJ) obstruction, even if function is poor, the kidney has a significant capacity for improvement in function following neonatal pyeloplasty. Even with bilateral UPJ obstruction (characterized by bilateral hydronephrosis and a normal bladder), the amniotic fluid volume and pulmonary development typically are normal. Consequently, specific intervention, such as percutaneous drainage of the fetal kidney or early delivery to allow immediate urologic surgery, is unwarranted. These same principles apply to primary obstructive megaureter.[9]

The primary life-threatening congenital urologic anomalies include PUVs, urethral atresia, and prune belly syndrome, which are usually characterized by bilateral hydroureteronephrosis and a distended bladder that does not empty in a male fetus. Approximately one-third of infants with urethral valves eventually develop renal insufficiency or end-stage renal disease.[10] Although prune belly syndrome is considered non-obstructive, neonates with this condition frequently have renal insufficiency, in large part because of congenital renal insufficiency and also from renal deterioration in children with repeated episodes of pyelonephritis. Urethral atresia is nearly always fatal, because the kidneys are usually dysplastic. A severe adverse prognostic factor is oligohydramnios, which prevents normal pulmonary development. In fetuses with severe obstructive uropathy and renal dysplasia, neonatal demise usually results from pulmonary hypoplasia rather than chronic renal failure. Intuitively, it would seem that treatment of the obstructed fetal urinary tract by diverting the urine into the empty amniotic space might allow normal renal development to occur and restore amniotic fluid dynamics, stimulating lung development. Indeed, experimental procedures have been performed, including percutaneous placement of a vesicoamniotic shunt, creation of a fetal vesicostomy or pyelostomy, and even percutaneous urethral valve ablation through a miniscope.[11] Unfortunately, the complication rate is high, including shunt migration, urinary ascites, stimulation of preterm labor, and chorioamnionitis.[2,12] Furthermore, in most cases, irreversible renal dysplasia has already occurred, and although the procedure may be successful technically, often the baby is stillborn, dies of pulmonary hypoplasia, or is alive with end-stage renal disease.[13,14] Nevertheless, some fetuses may benefit from aggressive intervention if the kidneys do not have irreversible dysplasia. Unfavorable prognostic factors include[2,9]

- Prolonged oligohydramnios
- Renal cortical cysts
- Urinary Na >100 mEq/L, Cl >90 mEq/L, and osmolarity >210 mOsm/L
- beta2-microglobulin >6 mg/L
- Reduced lung area and thoracic or abdominal circumference

Unfavorable urinary electrolytes may reflect stale urine in the fetal urinary tract. Consequently, perinatal centers typically obtain two or three sequential samples, as subsequent samples yield fetal urine that is more reflective of true fetal renal function.[14]

GUIDELINES ON ANH

In 2010, the Society for Fetal Urology (SFU) published a consensus statement regarding the evaluation and management of ANH.[15] This document was a comprehensive attempt to provide a guide to antenatal and postnatal management of ANH, and identify areas of controversy and prioritize research endeavors. The SFU did not provide guidance on when a voiding cystourethrogram (VCUG) should be performed. With regard to antibiotic prophylaxis, the authors recommended that neonates with an increased risk of UTI (girls, uncircumcised boys, moderate to severe hydronephrosis, and familial VUR) should receive prophylaxis until the initial evaluation is completed and management is planned with the family. In 2012, the American Urological Association (AUA) was asked to establish formal guidelines for ANH, but they thought that the SFU was thorough and did not need updating. The European Society for Paediatric Urology has published recommendations on management of various congenital urinary tract malformations, but has not addressed ANH specifically.

In 2013, the Indian Society of Pediatric Nephrology published updated guidelines on ANH.[16] These recommendations were based on systematic reviews of the literature from 1990 to 2012. Level 1 recommendations included those applicable to most subjects based on consistent information.

Table 100.1 Genitourinary anomalies detectable by prenatal ultrasonography

Condition	Sex (ratio)	Frequency	Kidney(s)	Ureter(s)	Bladder	Amniotic fluid	Prognosis
Ureteropelvic junction obstruction (unilateral)	M/F (3–4:1)	1:2000	Hydronephrosis	Not seen	Normal	Normal	Good after surgical correction
Multicystic kidney (unilateral)	M/F (1:1)	1:3000	Large with cysts of variable size	Not seen	Normal	Normal	Normal
Primary obstructive megaureter	M/F (3:1)	1:10 000	Hydronephrosis	Dilated	Normal	Normal	Good after surgical correction
Ectopic ureterocele or ureter	M/F (1:6)	1:10 000	Large cyst; possible duplex kidney	Dilated	Normal or enlarged	Normal	Good after surgical correction
Posterior urethral valves	Male	1:8000	Bilateral hydronephrosis; possible cortical cysts	Dilated	Enlarged	Variable; diminished or absent in severe obstruction	Usually good after surgical correction or drainage; poor if oligo?hydramnios is present
Prune belly syndrome	Nearly always male	1:40 000	Bilateral hydronephrosis; possible cortical cysts	Dilated	Enlarged	Variable; diminished or absent if severely affected	Usually fair to good; may need surgical drainage; poor if oligohydramnios is present
Vesico-ureteral reflux	M/F (1:5)	1:100	Hydronephrosis if reflux high grade	Variable	Normal; dilated if reflux high grade	Normal	Good; may need surgical correction
Infantile polycystic kidney disease	M/F	1:6000–1:14000	Large, echogenic	Not seen	Small or not seen	Usually absent or severely diminished	Poor
Renal agenesis	M/F (2.0–2.5:1)	1:4000 (bilateral)	Not seen	Not seen	Not seen	Severely diminished or absent	Stillbirth
		1:1500 (unilateral)	Not seen	Not seen	Normal	Normal	Normal
Hydrocolpos	Female		May have hydronephrosis	Not seen	Normal	Normal	Good after surgical correction
Ovarian cyst	Female		Normal (cyst may be confused with kidney or bladder)	Not seen	Normal	Normal	Good after surgical correction

Level 2 recommendations were those that were based on equivocal or insufficient information. Highlights of the recommendations include the following:

1. It is recommended that ANH be diagnosed and its severity graded based on anteroposterior diameter (APD) of the fetal renal pelvis (1B). ANH is present if the APD is ≥4 mm in second trimester and ≥7 mm in the third trimester.
2. Termination of pregnancy is not recommended in fetuses with unilateral or bilateral ANH, except in presence of extrarenal life threatening abnormality (1D).
3. It is recommended that all newborns with history of ANH should have postnatal ultrasound examination within the first week of life (1B). In neonates with suspected PUVs, oligohydramnios, or severe bilateral hydronephrosis, ultrasonography should be performed within 24–48 hours of birth (1C). In all other cases, the ultrasound should be performed preferably within 3–7 days, or before hospital discharge (1C).
4. It is recommended that assessment of severity of postnatal hydronephrosis be based on the classification proposed by SFU or APD of the renal pelvis (1B).
5. It is recommended that neonates with normal ultrasound examination in the first week of life should undergo a repeat study at 4–6 weeks (1C). Infants with isolated mild unilateral or bilateral hydronephrosis (APD <10 mm or SFU grade 1–2) should be followed by sequential ultrasound alone, for resolution or progression of findings (1C).
6. It is recommended that a micturating cystourethrogram (MCU) be performed in patients with unilateral or bilateral hydronephrosis with renal pelvic APD >10 mm, SFU grade 3–4, or ureteric dilatation (1B). MCU should be performed early, within 24–72 hours of life, in patients with suspected lower urinary tract obstruction (1D). In other cases, the procedure should be done at 4–6 weeks of age. MCU is recommended for infants with antenatally detected hydronephrosis who develop a UTI (1C).
7. It is recommended that infants with moderate to severe unilateral or bilateral hydronephrosis (SFU grade 3–4, APD >10 mm) who do not show VUR should undergo diuretic renography (1C). Infants with hydronephrosis and dilated ureter(s) and no evidence of VUR should undergo diuretic renography (2C). The preferred radiopharmaceuticals are ^{99m}Tc-mercaptoacetyltriglycine (^{99m}Tc-MAG3), ^{99m}Tc-ethylenedicysteine (^{99m}Tc-EC), or ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA) (2D). The differential function is estimated and renogram curve inspected for pattern of drainage. Diuretic renography should be performed after 6–8 weeks of age (2D). The procedure may be repeated after 3–6 months in infants where ultrasound shows worsening of pelvicalyceal dilatation (2D).
8. It is suggested that surgery be considered in patients with obstructed hydronephrosis, and either reduced differential renal function or its worsening on repeat evaluation (2C). It is suggested that surgery be considered in patients with bilateral hydronephrosis or hydronephrosis in a solitary kidney showing worsening dilatation and deterioration of function (2D).
9. It is recommended that parents of all infants with antenatal or postnatal hydronephrosis be counseled regarding the risk of UTIs and need for prompt management (1B). It is recommended that infants with postnatally confirmed moderate or severe hydronephrosis (SFU 3–4; renal APD >10 mm) or dilated ureter receive antibiotic prophylaxis while awaiting evaluation (1C). It is recommended that all patients detected to have VUR receive antibiotic prophylaxis through the first year of life (1B).

More recently, a multidisciplinary consensus conference involving eight societies was held and included pediatric urologists, pediatric nephrologists, pediatric radiologists, and maternal–fetal medicine specialists.[17] The purpose was to try to standardize the fetal evaluation and early postnatal management of babies with ANH. For example, several different classification schemes had been published for significant and insignificant pelvicalyceal dilation. In addition, although the SFU 4-point grading scale is used by most pediatric urologists, most pediatric radiologists classify hydronephrosis into mild, moderate, and severe.

The US parameters include anterior–posterior renal pelvic diameter (APRPD), calyceal dilation, whether it involves the major and/or minor calyces, parenchymal thickness and appearance, normal or abnormal ureter, and normal or abnormal bladder.[17] Normal values for urinary tract dilation are APRPD:

Antenatal	16–27 weeks	<4 mm
	≥28 weeks	<7 mm
Postnatal	(>48 hours)	<10 mm

Assuming there is no calyceal dilation, the kidneys have a normal appearance, and the ureter and bladder are normal, then this is considered a normal study.

The consensus group then categorized ANH into antenatal and postnatal risk groups. For antenatal, there are two risk groups: low risk and high risk. For postnatal, there are three risk groups: low risk, intermediate risk, and high risk. The panel recommended that all seven urinary tract parameters be described in a written report.

For antenatal presentation, if the APRPD is 4–7 mm at 16–27 weeks or 7–10 mm at ≥28 weeks, and there is central or no calyceal dilation, the fetus is **UTD** ["urinary tract dilation"] **A1**, **Low Risk**. In follow-up, for UTD A1, the panel suggested one additional antenatal US at ≥32 weeks, and after birth, a renal US at >48 hours to 1 month of age, and a second renal US 6 months later. Genetic screening is not indicated unless there are associated congenital malformations.

If the APRPD is ≥7 mm at 16–27 weeks or ≥10 mm at ≥28 weeks with any peripheral calyceal dilation or any other upper urinary tract abnormality, they are classified as **UTD A2-3** or **Increased Risk**. The assigned risk is based on the most concerning feature. For UTD A2-3, the panel recommended a follow-up US in 4–6 weeks, although with suspected PUVs or severe bilateral hydronephrosis, more frequent follow-up was recommended until delivery. Following delivery, a renal US after 48 hours but before 1 month was suggested, again with more immediate evaluation if PUV is suspected or there is significant bilateral hydronephrosis. In addition, specialist consultation with pediatric urology or nephrology was recommended.

For postnatal presentation, at >48 hours, an APRPD <10 mm is **Normal**. If the APRPD is 10–15 mm, there is central calyceal dilation, and all other parameters are normal, it is classified **UTD P1, Low Risk**. SFU hydronephrosis grades 1 and 2 correspond to UTD P1. The panel recommends a follow-up renal US in 1–6 months. A VCUG and antibiotic prophylaxis are optional, at the discretion of the clinician. A renal scan is not recommended.

If the postnatal APRPD is ≥15 mm, there is peripheral calyceal dilation, and/or abnormal ureters, it is classified **UTD P2, Intermediate Risk**. SFU hydronephrosis grade 3 corresponds to UTD P2. The panel recommends a follow-up renal US in 1–3 months. A VCUG, antibiotic prophylaxis, and a functional renal scan are optional, at the discretion of the clinician.

If the APRPD is ≥15 mm, and there is peripheral calyceal dilation, abnormal parenchymal thickness, abnormal parenchymal appearance, abnormal ureters, and/or abnormal bladder, it is classified **UTD P3, High Risk**. SFU hydronephrosis grade 4 corresponds to UTD P3. The panel recommends a follow-up renal US in 1 month. A VCUG and antibiotic prophylaxis are recommended. A functional renal scan is optional, at the discretion of the clinician (but is virtually always recommended).

This classification scheme was validated at the NIH Consensus Conference by the participants. In addition, it was evaluated in a retrospective study of 490 patients.[18] The authors found that the Urinary Tract Dilation classification appropriately identified the babies that were likely to require surgical intervention, while the SFU hydronephrosis grading system was most likely to predict likelihood of resolution of hydronephrosis.

MANAGEMENT OF THE NEWBORN WITH ANH

Management in the nursery

At birth, the abdomen is inspected to detect the presence of a mass, which most often is secondary to a multicystic dysplastic kidney or UPJ obstruction. In male newborns with PUVs, often a walnut-shaped mass, representing the bladder, is palpable just superior to the pubic symphysis. Newborns should also be evaluated for anomalies involving other organ systems, as urinary tract abnormalities often occur in babies with congenital heart disease, lung abnormalities, and anorectal malformations. Renal function should be monitored with serial serum creatinine levels, particularly in infants with bilateral hydronephrosis. At birth, the serum creatinine level is identical to the mother's, but by 1 week of age, the creatinine should decrease to 0.4 mg/dL. The exception is premature infants, in whom the creatinine may not decrease until these children reach 34–35 weeks' conceptional age because of renal immaturity before that age.

Antibiotic prophylaxis

Neonates with hydronephrosis who are at risk for UTI should be placed on antibiotic prophylaxis with either amoxicillin 50 mg daily or cephalexin 50 mg daily. At 2 months beyond term, the prophylaxis is usually changed to trimethoprim-sulfamethoxazole suspension or nitrofurantoin. In addition, circumcision should be considered in male neonates to minimize the likelihood of UTI. However, which babies are at risk and therefore who needs prophylaxis is controversial. Clearly, the risk group UTD P3, High Risk deserves prophylaxis. However, there is significant variability among pediatric urologists and nephrologists in prescribing prophylaxis for children with hydronephrosis.[19] For example, 30% of Canadian pediatric nephrologists would recommend CAP for bilateral low-grade ANH compared with 11% of pediatric urologists. With high-grade ANH, 73% of nephrologists and 38% of urologists recommended CAP. Their recommendations for VCUG also were quite variable.[19]

Early studies suggested that children with VUR, ectopic ureter and ureterocele, and PUVs benefit from prophylaxis, but that those with hydronephrosis secondary to an abnormality of the UPJ or ureterovesical junction are not at increased risk.[20] More recently, infants with high-grade hydronephrosis (OR 2.40), female gender (OR 3.16), and uncircumcised males (OR 3.63) were at highest risk, and multivariate analysis suggested that prophylaxis was not beneficial.[21] However, a subsequent prospective study from the same institution indicated that "lack of continuous antibiotic prophylaxis," hydroureteronephrosis, and VUR were significant risk factors of febrile UTI.[22] Similarly, Herz et al.[23] demonstrated in a retrospective study that the risk of febrile UTI was 7.9% in children receiving prophylaxis vs. 18.7% in those not receiving prophylaxis. In that study, children with ureteral dilation >11 mm, ureterovesical obstruction, and high-grade VUR were at greatest risk for a febrile UTI. Most agree that children with low-grade hydronephrosis do not benefit from prophylaxis.[24,25] Antibiotic resistance is a definite concern when prescribing prophylaxis unnecessarily.[26]

INITIAL RADIOLOGIC EVALUATION

Radiologic evaluation should be performed to delineate the abnormality responsible for changes on prenatal

sonography. Serial renal sonograms, a VCUG, and a diuretic renogram usually provide the diagnostic information necessary to guide management, although all of these studies are unnecessary in many children.

Renal ultrasound

A renal and bladder sonogram should be obtained first. Because neonates have transient oliguria, a dilated or obstructed collecting system may appear normal for the first 24–48 hours of life (Figure 100.1). Ideally, if unilateral hydronephrosis was present prenatally, the renal sonogram should not be obtained until 72 hours to maximize its sensitivity, and unless the antenatal US showed severe unilateral or bilateral hydronephrosis, it is most appropriate to wait until 1–2 weeks of age.

Renal length, degree of caliectasis and parenchymal thickness, and presence or absence of ureteral dilation should be assessed. The severity of hydronephrosis can be graded from 1 to 4 using the SFU grading scale (Figure 100.2).[27] Inexperienced radiologists may misinterpret a normal neonatal kidney with hypoechoic pyramids for caliectasis. Most significant urologic anomalies that require surgical correction or long-term urological follow-up are associated with grade 3 or 4 hydronephrosis.[28] More sophisticated analyses, such as the renal resistive index, as well as urinary studies have been assessed, but efforts to demonstrate obstruction have been inconsistent. The degree of pelvocaliectasis correlates closely with the likelihood that a significant urological condition is present. Lee et al.[29] performed a meta-analysis of reports of ANH and determined that the risk of finding postnatal pathology was 11.9% with mild ANH, 45.1% for moderate, and 88.3% for severe ANH. Their definitions of mild, moderate, and severe hydronephrosis depended on gestational age at the time of diagnosis. Similarly, Sidhu et al.[30] performed a meta-analysis and found that when postnatal hydronephrosis was SFU grade 1 or 2, there was stabilization or resolution of pelviectasis in 98%, whereas when there was SFU grade 3 or 4, there was stabilization or resolution in only 51%. Madden-Fuentes et al.[31] reported 416 infants with low-grade hydronephrosis. Of 398 renal units with grade 1 hydronephrosis, 96.7% resolved or remained stable; 3.3% worsened, and only one underwent ureteroneocystostomy. Of 225 units with grade 2 hydronephrosis, 98.7% resolved, improved, or remained stable, whereas 1.3% worsened, and one underwent a pyeloplasty. Only 0.7% had a febrile UTI.

The bladder should be imaged to detect a dilated posterior urethra (urethral valves), bladder wall thickening,

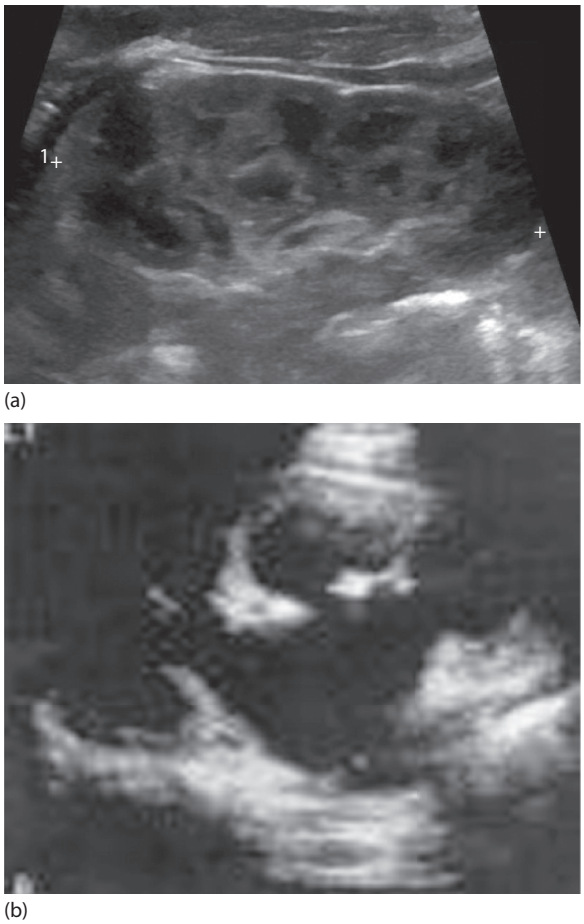

Figure 100.1 Newborn with prenatal diagnosis of left hydronephrosis. **(a)** Ultrasound of left kidney taken shortly after birth. Normal study. Echolucent areas in renal cortex are pyramids (normal finding). **(b)** Same patient. Ultrasound of left kidney at 6 weeks shows grade 4 hydronephrosis.

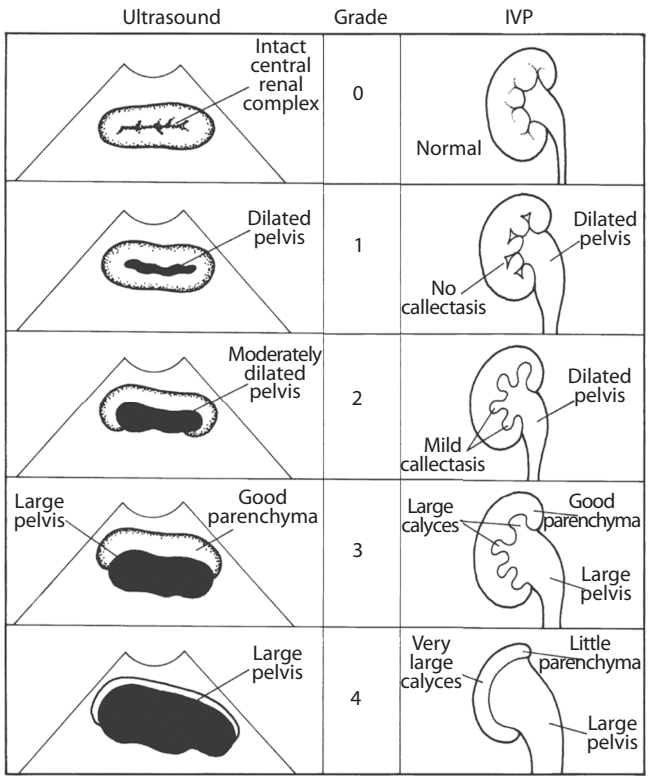

Figure 100.2 Grading system for hydronephrosis. (Reproduced with permission from the Society for Fetal Urology.)

ureteral dilation, inadequate bladder emptying, or a ureterocele. Perineal sonography may demonstrate a dilated prostatic urethra, which is consistent with PUVs.

Voiding cystourethrogram

In selected cases, a VCUG should be performed. This study may demonstrate VUR, PUVs, or a bladder diverticulum. A radiographic cystogram is preferred over a radionuclide cystogram because the latter does not provide sufficient delineation of bladder and urethral anatomy and because VUR, if present, cannot be graded. In a recent analysis by the AUA Pediatric Vesicoureteral Reflux Guidelines Committee, an overall VUR detection rate of 16.2% was found.[32] The mean incidence of VUR into a nondilated kidney was 4.1%. In cases with ANH and a normal postnatal sonogram, the incidence of VUR was 17%. The prevalence of VUR was significantly higher in girls than boys with ANH. The likelihood is highest if there is SFU grade 3 or 4 hydronephrosis or if a dilated ureter is identified. The chance of identifying VUR on a VCUG is less if there is only SFU grade 1 or 2.[33]

WHAT IF THE INITIAL SONOGRAM IS NORMAL?

A common dilemma is whether a full evaluation is necessary if the initial renal sonogram is normal. Assuming a significant degree of fetal renal pelvic dilatation (i.e., >4 mm anteroposterior pelvic diameter before 33 weeks, 7 mm diameter after 33 weeks) was present, the child may have VUR. This issue is unresolved. For example, Blane et al.[34] reported that 12% of children with grade V, 31% with grade IV, and 80% with grade III VUR had a normal renal sonogram. However, the AUA Reflux Guidelines determined that the mean incidence of VUR into a nondilated kidney was 4.1%.[32] Because VUR may cause intermittent renal pelvic dilation, theoretically babies with prenatal hydronephrosis and a normal postnatal sonogram may have VUR, and early diagnosis and medical treatment of VUR may reduce the likelihood of developing reflux nephropathy.[35] On the other hand, others have advocated performing a VCUG only if the postnatal sonogram is abnormal; however, in these reports, neonates with a normal postnatal renal sonogram were not systematically evaluated to determine the real incidence of VUR in this group. Currently, most do not recommend a VCUG unless the postnatal renal sonogram demonstrates grade 3 or 4 hydronephrosis and/or ureteral dilation.

Follow-up evaluation and treatment

If bilateral hydronephrosis or unilateral hydronephrosis in a solitary kidney is present, then close monitoring of the serum creatinine and electrolytes is necessary. If the hydronephrosis is caused by PUVs, then valve ablation should be performed before hospital discharge. If the hydronephrosis is secondary to VUR, the infant should be placed on prophylaxis and managed, as described later in this chapter. If the hydronephrosis is grade 3 to 4 and bilateral UPJ or ureterovesical junction obstruction is suspected, prompt evaluation with diuretic renography is indicated. If unilateral hydronephrosis and a normal contralateral kidney are present, abnormalities in serum creatinine or electrolytes are uncommon. Nevertheless, these serum studies should be drawn to document that renal function is normal. Usually, follow-up functional radiographic studies can be delayed until 4–6 weeks of age, when renal function is more mature and studies of renal function and obstruction are more likely to be accurate. If the sonogram and VCUG are normal, then only a follow-up sonogram in 6–8 weeks is necessary. In general, if hydronephrosis is discovered on the initial postnatal sonogram, pediatric urologic or nephrologic consultation is advisable to direct subsequent radiologic evaluation and plan therapy.

Diuretic renogram

The diuretic renogram is used to determine whether upper urinary tract obstruction is present.[36] It is used to assess differential renal function and efficiency of drainage of the kidneys. Infants with grade 3 and 4, and occasionally grade 2, hydronephrosis should undergo this study. Mercaptoacetyltriglycine (MAG-3) is generally used and is secreted by the renal tubules. It provides excellent images with minimal background activity. During a diuretic renogram, a small dose of the radiopharmaceutical is injected intravenously. During the first 2–3 minutes, renal parenchymal uptake is analyzed and compared, allowing computation of differential renal function. Subsequently, excretion is evaluated. After 20–30 minutes, furosemide is injected intravenously, and the rapidity and pattern of drainage from the kidneys to the bladder are analyzed. If no upper urinary tract obstruction is present, then normally half of the radionuclide is cleared from the renal pelvis within 10–15 minutes, termed the t½. A t½ >20 minutes is consistent with upper urinary tract obstruction, but is not diagnostic of obstruction, because there are factors that can prolong the t½ in addition to an obstructive lesion (see below). A t½ between 15 and 20 minutes is indeterminate. The images generated usually provide an accurate assessment of the site of obstruction.

Numerous variables affect the outcome of the diuretic renogram. For example, newborn kidneys are functionally immature, and in some cases, even normal kidneys may not demonstrate normal drainage following diuretic administration. Dehydration prolongs parenchymal transit and can blunt the diuretic response. Giving an insufficient dose of furosemide may result in slow or inadequate drainage. In addition, a full bladder may impede bladder drainage. Furthermore, if VUR is present, continuous catheter drainage is mandatory to prevent the radionuclide from refluxing from the bladder into the dilated upper tract, causing a prolonged washout phase. Consequently, a urethral catheter should be inserted and bladder drainage measured.

Magnetic resonance urography

The newest study used to evaluate suspected upper urinary tract pathology is magnetic resonance urography (MRU) (Figure 100.3). The child is hydrated and given i.v. furosemide. Next, gadolinium-DTPA, which is filtered and excreted, is injected intravenously, and routine T1-weighted and fat-suppressed fast spin-echo T2-weighted imaging is performed through the kidneys, ureters, and bladder. This study provides superb images of the pathology, and methodology is being developed to allow assessment of differential renal function and drainage.[37] There is no radiation exposure, but younger children need sedation or general anesthesia. It is the procedure of choice for delineating complex genitourinary pathology (e.g., cross-fused ectopia with hydronephrosis and/or segmental multicystic kidney, cloacal anomaly).

Ancillary studies

In most cases, a renal sonogram, VCUG, and diuretic renogram provide sufficient information to establish a diagnosis and establish a plan of management. In particularly complicated cases, however, cystoscopy with retrograde pyelography, computed tomography (CT) scan, antegrade pyelography, or a Whitaker antegrade perfusion test is necessary.

CONGENITAL ANOMALIES CAUSING ANH

UPJ obstruction or anomalous UPJ

The most common cause of severe hydronephrosis without a dilated ureter or bladder in newborn infants is UPJ obstruction, which results from an intrinsic fibrotic narrowing at the junction between the ureter and renal pelvis (Figure 100.4). At times, an accessory artery to the lower pole of the kidney also causes extrinsic obstruction, but this finding is rare in newborns with hydronephrosis; it is much more likely to occur in older children and adults. In kidneys with a UPJ obstruction, renal function may be significantly impaired from pressure atrophy.

The anomaly is corrected by performing a pyeloplasty, in which the stenotic segment is excised and the normal ureter and renal pelvis are reattached. Success rates are 91%–98%. Lesser degrees of UPJ narrowing may cause mild hydronephrosis, which is usually non-obstructive, and typically these kidneys function normally. Another cause of mild hydronephrosis is fetal folds of the upper ureter (Figure 100.5), which also are non-obstructive. The spectrum of non-obstructive UPJ abnormalities often is termed "anomalous UPJ."

Hydronephrosis in many newborns gradually diminishes or resolves over months to years. The goal of early evaluation is to determine whether a true anatomic obstruction is present that should be corrected or whether it is safe to follow the infant non-operatively. Defining what constitutes obstructive and non-obstructive hydronephrosis is a constant source of debate in pediatric urology. Cartwright et al.[38] studied 80 neonates with suspected UPJ obstruction. Of 39 with unilateral hydronephrosis and at least 35% differential renal function who were managed non-operatively, only 6 (15%) later underwent pyeloplasty, primarily because of deteriorating differential renal function on renal scintigraphy. Following pyeloplasty, the differential renal function returned to its initial level in these patients. One might question whether early pyeloplasty in these patients would have allowed renal function to improve to 50% (normal). The remaining patients managed non-operatively maintained differential function greater than 40%. Koff and Campbell[39] reported 104 consecutive neonates with unilateral hydronephrosis managed non-operatively, with follow-up as long as 5 years. In follow-up, only seven (7%) underwent pyeloplasty because of reduction in differential renal function of more than 10% or progression of hydronephrosis. Pyeloplasty returned differential renal function to prepyeloplasty levels in all cases. Of 16 patients with significantly reduced renal function on initial scan and grade 4 hydronephrosis, rapid improvement was noted on follow-up, diuretic renography in 15, and the washout curve became non-obstructive in 6. In addition, hydronephrosis disappeared in six, improved in six, remained stable in three, and deteriorated in one. The physiology of the resolution or reduction in hydronephrosis and the improvement in differential renal function in these babies is unknown. In another more recent report from the same institution, of

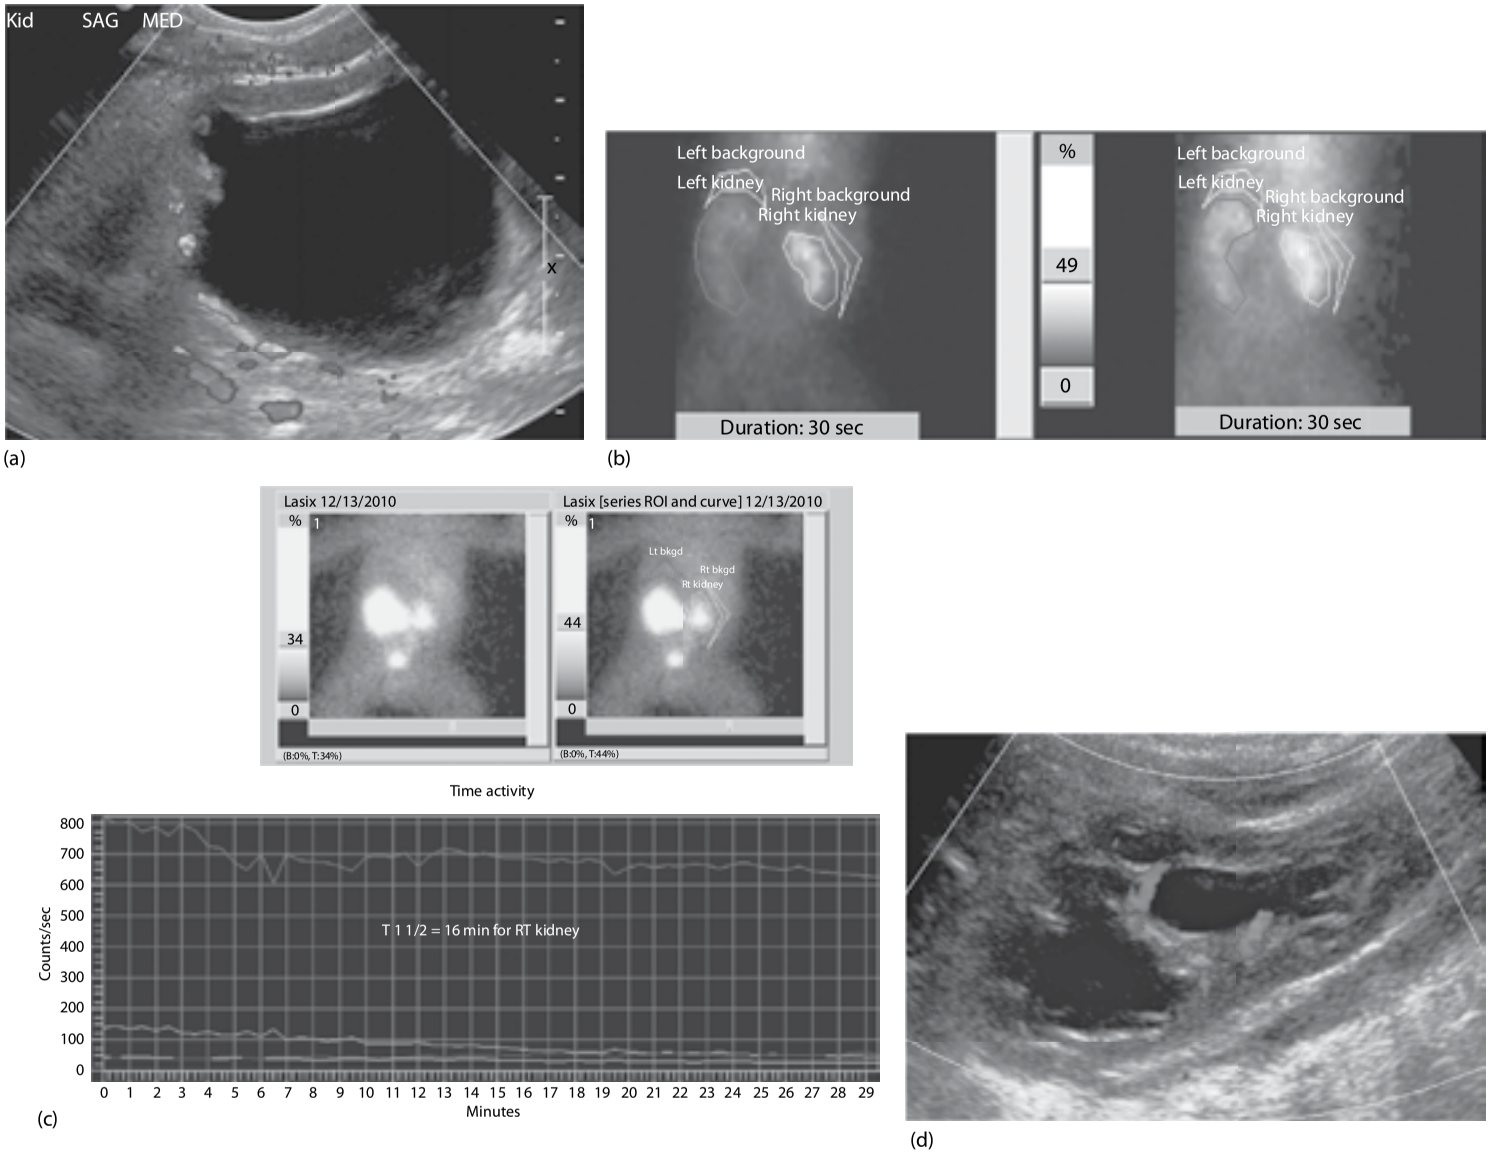

Figure 100.4 Newborn with prenatal diagnosis of left hydronephrosis. **(a)** Sonogram left kidney demonstrates grade 4 left hydronephrosis without a dilated ureter. The voiding cystourethrogram was normal. **(b, c)** MAG-3 diuretic renogram (left kidney on the left side of image) shows minimal drainage on the left side. The differential function left:right was 46:54%. Patient underwent left pyeloplasty at 2 months of age. **(d)** Follow-up sonogram of left kidney at 5 months of age demonstrates reduction in hydronephrosis.

Figure 100.5 Excretory urogram in infant with bilateral grade 2 hydronephrosis shows bilateral fetal folds of upper ureters (arrows). Note sharp calyces (normal).

19 newborns with bilateral grade 3 or 4 hydronephrosis, a total of 13 kidneys were subjected to pyeloplasty.[40] Of those managed non-operatively, 21 kidneys were grade 0 to 2 and grade 3 in 2 kidneys. The mean follow-up time to achieve maximum improvement in hydronephrosis was 10 months.

Although these studies suggest that it is safe or appropriate to manage neonates with a suspected UPJ obstruction non-operatively, an infant's kidney has much greater capacity for improvement in differential renal function than an older child's. In addition, all of these studies base "differential renal function" on the uptake during the first 2–3 minutes of the study, and there is substantial variability in the way this percentage is calculated.[41] Finally, these studies have not reported the pattern of washout on diuretic renography. In a review of renal biopsies obtained at pyeloplasty at the author's previous institution, 63% showed minimal or no obstructive histologic changes; however, of those with differential function greater than 40%, 21% showed significant histopathologic changes, including reduced glomerular number, glomerular hyalinization, interstitial inflammation, and dysplastic glomeruli.[42] Of the kidneys with a differential function less than 40%, 33% showed minimal or no histologic changes. Overall, in 25% of the patients, the findings on renal biopsy did not correlate with the computed differential renal function and reflect the need for more sensitive markers of obstruction. The approach of most pediatric urologists to neonates with a suspected UPJ obstruction is as follows. The hydronephrosis is graded from 1 to 4 using the SFU grading scale and a VCUG is obtained. Nearly all infants requiring pyeloplasty have grade 3 or 4 hydronephrosis, and those with grade 1 or 2 hydronephrosis do not seem to be at significant long-term risk. If a neonate has an abdominal mass from a hydronephrotic kidney, bilateral severe hydronephrosis, or a solitary kidney, a prompt MAG-3 diuretic renogram is obtained. If signs of obstruction are apparent, prompt pyeloplasty is performed. Otherwise, the newborn is placed on amoxicillin 50 mg daily for prophylaxis, and the diuretic renogram is obtained at 6 weeks of age. The study is not obtained right away in these cases because renal function in the newborn is immature. If diuretic renography shows at least >40% differential renal function and there is some drainage on the diuretic renogram, the child can be managed non-operatively, regardless of the drainage pattern (Figure 100.4).[43] At 2 months, prophylaxis is changed to trimethoprim sulfamethoxazole suspension 1.25 mL daily. A follow-up renal sonogram is performed 3 months later. If the hydronephrosis is unchanged from baseline, a repeat MAG-3 diuretic renogram is obtained. If there is deterioration in differential renal function or worsening of the diuretic washout curve, pyeloplasty is recommended. However, if these parameters remain stable or improved and the child does not develop a UTI, follow-up 3–6 months later with another renal sonogram or MAG-3 diuretic renogram is performed, and management is individualized. It is incumbent on clinicians caring for these infants to have a good understanding of the vagaries of the diuretic renogram and to monitor infants with a suspected UPJ obstruction closely. In addition, review of the radiologic studies (not just the radiology report) by the pediatric urologist is important.

There has been significant progress in the development of minimally invasive techniques in pediatric pyeloplasty, even in infants. Although infant pyeloplasty is performed through a small incision (lumbotomy or flank muscle-splitting) in many centers,[44] an increasing number of pediatric urologists are performing the procedure with traditional laparoscopic techniques, or the daVinci robot.[45] Success rates are being compared to series of open surgical repair; hospital stay and narcotic use are less with the minimally invasive approach. Generally, a transperitoneal approach has been used, with mobilization of the colon. However, on the left side, the pyeloplasty can be performed with a transmesenteric approach.

Multicystic dysplastic kidney

A multicystic dysplastic kidney is composed of multiple noncommunicating cysts of varying sizes with a stromal component that is composed of dysplastic elements. These kidneys do not function. Although multicystic kidney is the most common cause of an abdominal mass in neonates, the vast majority of multicystic kidneys are detected by prenatal sonography. Some clinicians incorrectly assume that multicystic kidney and polycystic kidney are synonymous terms. Polycystic kidney disease is an inherited disorder and has an "adult form" (autosomal dominant) and an "infantile form" (autosomal recessive) and affects both kidneys. In contrast, a multicystic kidney is almost always unilateral

and is usually not an inherited disorder. Sonography of multicystic kidneys is often diagnostic, demonstrating multiple echolucent cysts of varying sizes with no discernible cortex (Figure 100.6). Occasionally, the cysts may resemble a severe UPJ obstruction with minimal parenchyma, termed the "hydronephrotic variant." The contralateral kidney is abnormal in 5%–10% of cases. Renal scintigraphy (MAG-3 or DMSA [dimercaptosuccinic acid] scan) shows nonfunction, but with current US techniques generally is unnecessary for confirmation.[46] On occasion, there is a segmental multicystic kidney, in which there is a complete duplication anomaly of the upper urinary tract, with the upper pole being multicystic.[47] Many also recommend obtaining a VCUG, because as many as 15% have contralateral VUR,[48] but currently it seems unnecessary unless there is contralateral hydronephrosis.[49]

The management of a multicystic kidney is becoming less controversial. If an abdominal mass that is symptomatic is present, early nephrectomy is indicated. However, left untreated, most multicystic kidneys become smaller. Potential complications include malignancy and hypertension. In a review of 26 clinical series, no cases of Wilms' tumor were reported among 1041 children, and the maximum estimated risk was 3.5 per 1000 affected children.[50] Tumors arise from the stromal, not the cystic, component of multicystic kidneys. Consequently, even if the cysts regress completely, the likelihood that the kidney could develop a neoplasm is not altered. With regard to hypertension, in a review of 29 studies, 6 cases were reported among 1115 eligible children, and the mean probability was 5.4 per 1000 affected children (95% confidence interval [CI] 1.9 to 11.7 per 1000).[51]

Generally, a follow-up sonogram is recommended at 6 months of age. If the cysts enlarge, the stromal core increases in size, or hypertension develops, laparoscopic (or possibly open) simple nephrectomy is recommended. However, further follow-up sonography is unnecessary unless there is concern regarding the contralateral kidney, because finding a Wilms' tumor incidentally would be extremely rare. Because of the occult nature of hypertension, annual blood pressure measurement is recommended, and if hypertension occurs, nephrectomy should be considered.

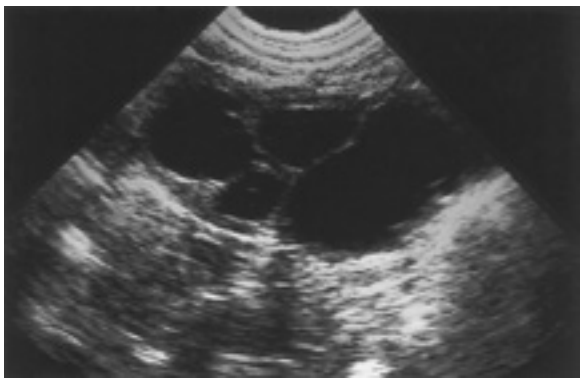

Figure 100.6 Left multicystic dysplastic kidney.

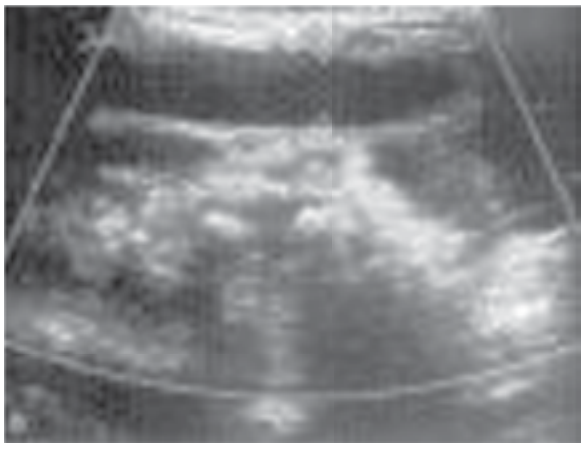
Primary obstructive megaureter (nonrefluxing)

A megaureter refers to a wide ureter and may be (1) primary or secondary, (2) obstructive or non-obstructive, and (3) refluxing or nonrefluxing. Nonrefluxing megaureter results from an aperistaltic segment of the distal ureter that does not allow normal propulsion of urine (Figure 100.3). In this condition, sonography shows a dilated ureter and renal pelvis with variable renal parenchymal atrophy. VCUG shows no VUR in most cases. Before the antenatal sonography era, most patients with this condition presented with flank pain, flank mass, pyelonephritis, hematuria, or stone disease. Surgical correction consists of excision of the aperistaltic segment, tailoring (also known as tapering) of the ureter, and reimplantation of the ureter into the bladder. Although severe hydronephrosis may be present, often there is a tendency to gradual reduction in hydronephrosis over a period of several years (Figure 100.7). Braga et al.[52] reported that the majority of their patients demonstrated resolution of hydronephrosis in a median of 17 months, although those with a mean ureteral diameter >17 mm required surgical intervention. This group found that continuous antibiotic prophylaxis and circumcision reduced the risk of UTI. DiRenzo et al.[53] found that resolution or improvement of hydronephrosis occurs in all cases of mild postnatal dilation and 60% of those with moderate or severe upper urinary tract dilatation. The British Association of Paediatric Urologists recommends initial non-operative management of primary obstructive megaureter.[54] In follow-up, surgical intervention is recommended for UTI, pain, worsening hydronephrosis, differential renal function <40%, or a significant drop in renal function. Consequently, most of these patients may be followed non-operatively on antibiotic prophylaxis and serial monitoring of renal function and drainage.

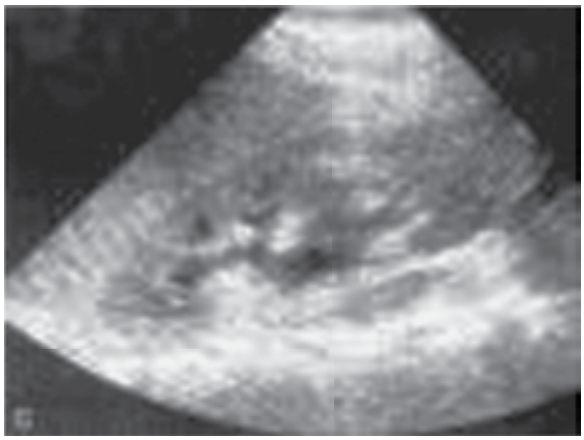
In neonates with an antenatal diagnosis of hydroureteronephrosis, a renal sonogram and VCUG should be obtained. Early management is identical to that of neonates with suspected UPJ obstruction. If an abdominal mass, solitary kidney, or bilateral hydroureteronephrosis is present, then a MAG-3 diuretic renogram should be obtained promptly. Otherwise, the study is deferred until 6–8 weeks of age. In some centers, the diuretic-stimulated drainage from the renal pelvis and ureter are measured separately. If the differential renal function is at least 40%, the child generally is managed non-operatively, even with grade 4 hydronephrosis, and a follow-up renal sonogram or diuretic renogram is obtained every 3–6 months. These infants should receive prophylactic antibiotics while stasis is present in the upper ureter and kidney.

Early repair of megaureter has a higher complication rate than in older children. For example, Peters et al.[55] reported on megaureter repair in 42 infants operated on at



(a)

(b)



(c)

Figure 100.7 Female newborn with nonrefluxing left megaureter discovered by prenatal ultrasound. **(a, b)** Newborn ultrasound shows grade 4 hydronephrosis and dilated ureter. Diuretic renogram, 8 weeks of age, showed 50% differential renal function in left kidney. Obstructive drainage pattern was noted following administration of furosemide. Patient managed nonoperatively. **(c)** Ultrasound 6 months later shows grade 1 hydronephrosis. Diuretic renogram later showed normal drainage pattern.

a mean age of 1.8 months. In that series, early complications occurred only in those less than 6 weeks of age and included transient apnea in three, UTI in one, hyponatremia in one, and meningitis in one. VUR occurred postoperatively in six infants, and none developed postoperative obstruction. The VUR resolved spontaneously between 18 and 36 months in three patients, and the remainder underwent secondary ureteroneocystostomy. Greenfield et al.[56] reported on repair of 11 megaureters in infants less than 6 months old. Of these children, two had transient ureteral obstruction immediately after stent removal and persistent grades I and II VUR in two children. In a series of older children who underwent tapered ureteral reimplantation, the success rate was 90% for obstructive megaureter.[57] The results were slightly better for intravesical compared with extravesical reimplantation.

There are three other treatment options if surgical repair seems necessary in the neonate or young infant. The first is to perform a temporary cutaneous ureterostomy, allowing the ureter to decompress over a period of 12–18 months. Subsequently, the ureterostomy can be taken down and ureteral reimplantation with or without tapering is performed. In a series of children who underwent this procedure, when undiversion and ureteral reimplantation were performed, only 5 of 23 ureters required tapering.[58] Another option is temporary refluxing ureteral reimplantation, in which the ureter is anastomosed end-to side to the bladder, and performing traditional ureteral reimplantation when the child is older.[59] The other option is to insert a double J ureteral stent through the ureterovesical junction and leave it interposed between the bladder and the kidney. Farrugia et al.[60] reported a series of 19 megaureters that were stented at a median age of 6 months, 1/3 endoscopically. Nearly 1/3 had stent-related complications, but 50% had improvement in upper tract drainage following stent removal.

In summary, if differential renal function remains normal and the child is asymptomatic, it seems safe to follow these patients with renal sonograms and diuretic renography to monitor hydronephrosis, and renal function and drainage. If renal functional deterioration, slowing of upper urinary tract drainage, or UTI occurs, ureteral reimplantation is recommended.

Ureterocele and ectopic ureter

A ureterocele is a cystic dilatation of the distal end of the ureter and is usually obstructive. In children, they usually extend through the bladder neck, termed "ectopic," but may remain entirely within the bladder, termed "intravesical" or "orthotopic." Ectopic ureteroceles and ectopic ureters occur more commonly in girls than in boys and usually are associated with the upper pole of a completely duplicated collecting system. In boys with a ureterocele, however, 40% drain a single collecting system. Prenatal sonography typically shows either hydroureteronephrosis or upper pole hydronephrosis with a dilated ureter. These conditions are bilateral in 10%–15% of patients.

Early evaluation consists of the following:

– Sonography shows a hydronephrotic upper pole connected to a dilated ureter; the ureterocele typically is visualized in the bladder (Figure 100.8a,b).
– VCUG often visualizes the ureterocele and demonstrates whether VUR is present, either into the lower pole moiety or contralateral collecting system (Figure 100.8c); an ectopic ureter that inserts into the bladder neck also typically refluxes into the upper pole obstructed ureter.
– DMSA or MAG-3 renal scan shows whether the moiety drained by the ectopic system functions; this study may be done at 1–2 weeks of age because the result does not change with functional maturity. Alternatively, a CT or MRU demonstrates the anatomy adequately, although it may not provide functional information regarding the obstructed upper pole (Figure 100.8c).

The management of neonates with a ureterocele is highly individualized.[61] The least invasive initial form of therapy is transurethral incision (TUI), which can be performed either with a 3-F Bugbee electrode or the holmium:YAG laser (Figure 100.8d,e). The ureterocele is punctured several times at its junction with the bladder mucosa. If the ureterocele is ectopic, it must be punctured both in the bladder and in the urethra. TUI provides satisfactory upper tract decompression with a single procedure in >90% of cases. However, there is a significant risk of postoperative VUR through the ureterocele into the upper pole moiety, which may require subsequent definitive treatment. If the ureterocele is orthotopic, approximately 30% show VUR following TUI, whereas if it is ectopic, 75% have VUR following TUI.[62,63] TUI is often the only procedure necessary.[64] TUI of a ureterocele draining a nonfunctioning moiety will not result in the development of any significant degree of function. In recent years, many centers have been performing minimally invasive (laparoscopic) upper pole heminephrectomy. These

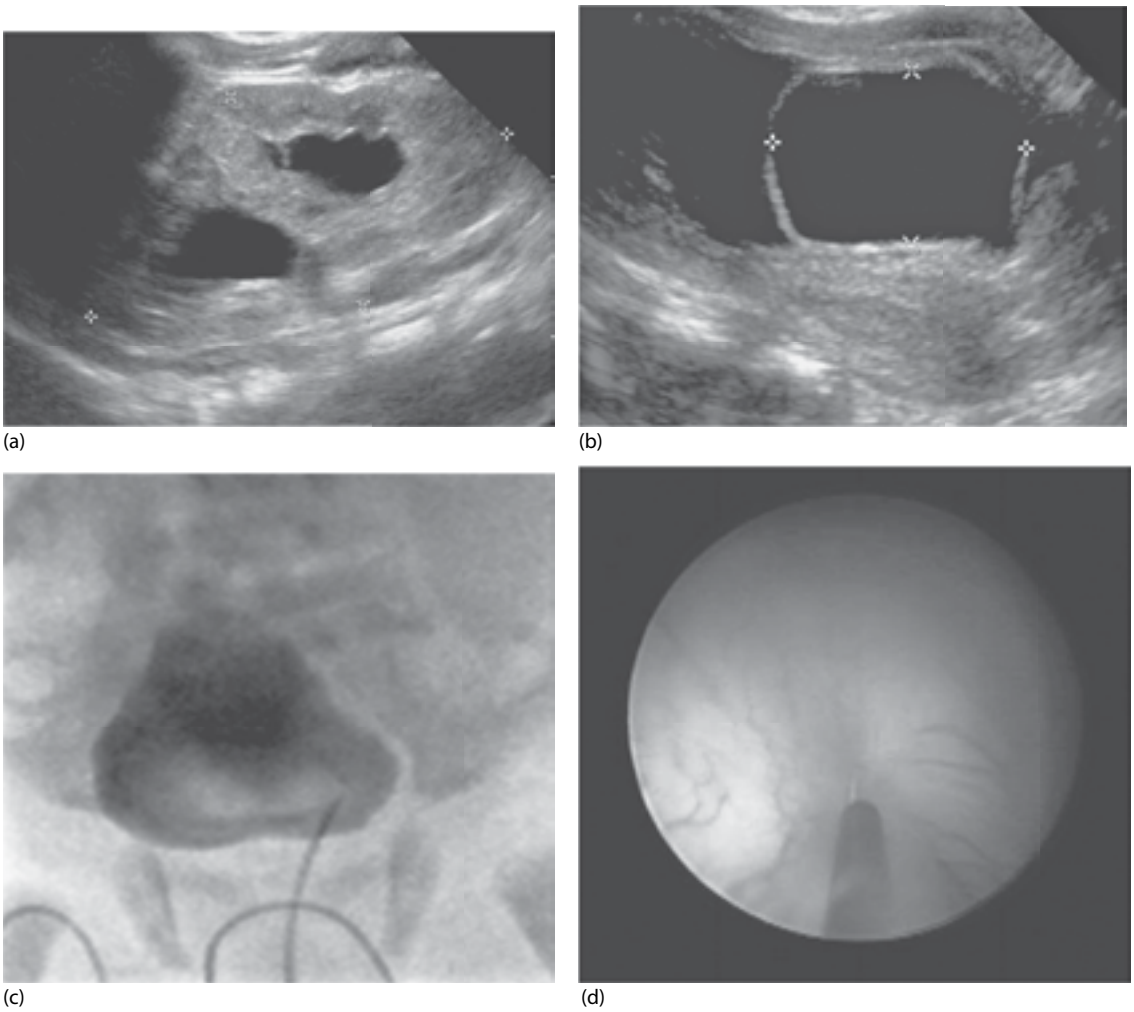


Figure 100.8 Infant with ureterocele and duplex collecting system, right side. **(a)** Sonogram of right kidney demonstrating echogenic right kidney with duplex collecting system and hydronephrosis involving both upper and lower pole. **(b)** Ureterocele in bladder. **(c)** Voiding cystourethrogram shows ureterocele in bladder, and no vesicoureteral reflux. **(d)** Patient underwent transurethral incision; endoscopic view of ureterocele. procedures have been performed either with a retroperitoneal[65] or transperitoneal[66] approach. One recent series with a laparoscopic retroperitoneal approach reported an overall conversion rate to open surgery of 21%, although the authors stated that they had only one conversion in their most recent 20 cases.[67] Common complications include perirenal urinoma and, in some cases, devascularization of the lower pole moiety. The latter complication is most common in infants. Another option is to perform transperitoneal laparoscopic partial nephrectomy with robotic assistance.[68] Consequently, if the hydronephrotic upper pole does not function, this author maintains the infant on antibiotic prophylaxis and laparoscopic upper pole heminephrectomy (or nephrectomy, if the entire kidney does not function) with or without robotic assistance performed electively at 6 months of age, assuming the upper pole system remains hydronephrotic. If the renal scan shows significant upper pole function, however, ureteropyelostomy or ureteroureterostomy, in which the upper pole ureter is anastomosed to the lower pole renal pelvis or ureter, is recommended. This procedure can be performed either at the level of the kidney, with removal of part of the redundant distal ureter,[69] or low, through an inguinal incision.[70] Total urinary tract reconstruction in neonates and infants is not recommended because of the high complication rate caused by the small size of the infant bladder.

Posterior urethral valves

The most common cause of severe obstructive uropathy in children is PUVs, which are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter (Figure 100.9).[10] Typically, the leaflets are separated by a slit-like opening. Approximately one-third ultimately develop chronic renal failure or severe renal insufficiency. Prognosis is significantly better if the antenatal sonogram before 24 weeks' gestation was normal. In one study, 9 of 17 patients with PUV whose hydronephrosis was discovered before 24

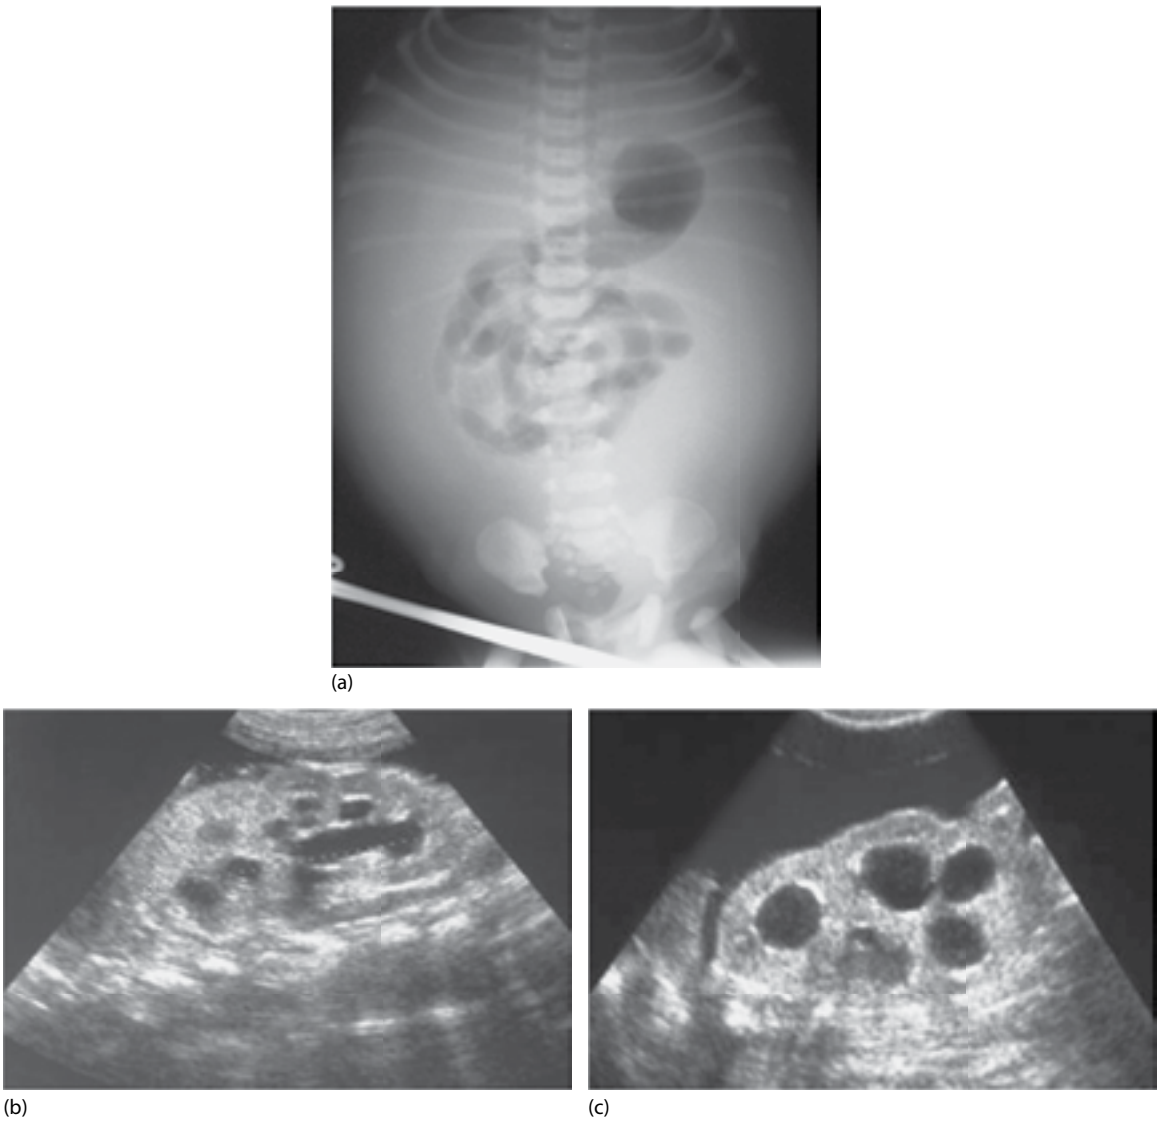

Figure 100.9 Newborn with posterior urethral valves and abdominal distension secondary to urinary ascites. **(a)** Plain film of abdomen showing ascites. **(b, c)** Renal sonogram showing bilateral hydronephrosis and urinary ascites. (*Continued*)

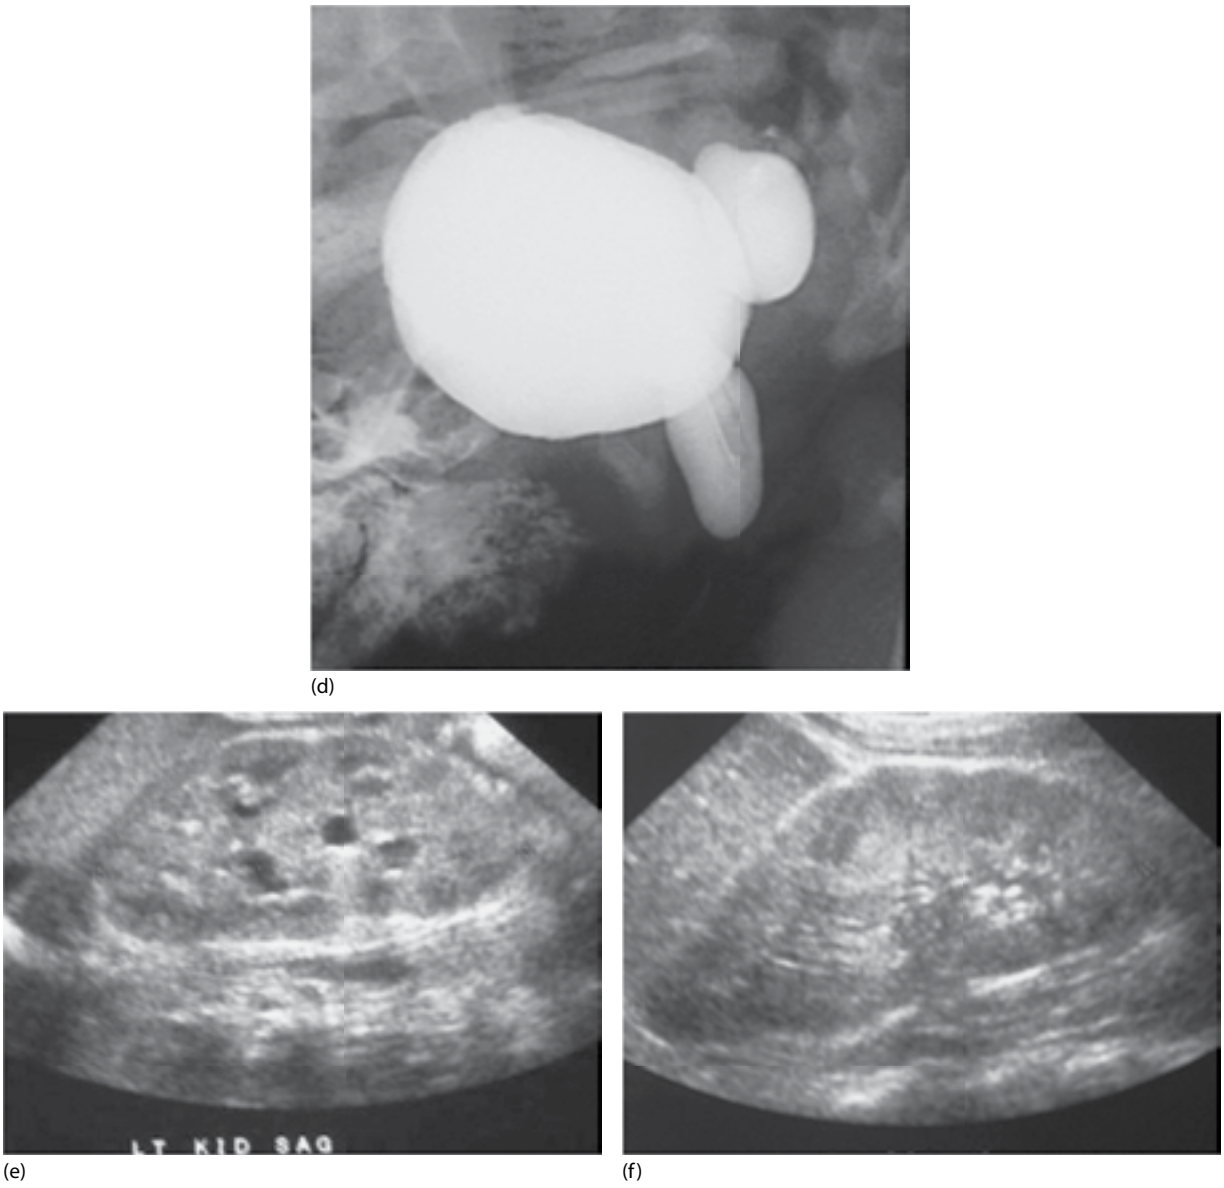
weeks' gestation developed renal failure, whereas only 1 of 14 recognized after 24 weeks' gestation developed end-stage renal disease.[71] Favorable prognostic factors include a serum creatinine level of less than 0.8–1.0 mg% after bladder decompression, unilateral VUR into a nonfunctioning kidney ("VURD syndrome"), ascites, and identification of the corticomedullary junction on renal sonography. Early delivery of infants with an antenatal diagnosis of suspected PUV is not recommended, unless there is oligohydramnios. If severe bilateral renal dysplasia is present, pulmonary hypoplasia is often also present, and problems with ventilation may result. Initially, a small feeding tube should be passed into the bladder for urinary drainage until electrolyte imbalances can be corrected. A Foley catheter is not recommended because the balloon may cause significant bladder spasm and impede upper tract drainage. Care should be taken passing the catheter, as the prostatic urethra is dilated and there is bladder neck hypertrophy; the feeding tube may coil in the prostatic urethra and not drain the bladder. In this setting, catheter irrigation typically results in fluid coming out of the urethra next to the catheter. AVCUG should be obtained to confirm the diagnosis, and a renal scan should be performed to evaluate the upper tract differential renal function.[10] In newborns, alternative treatments include transurethral endoscopic ablation of PUV, cutaneous vesicostomy, and high diversion (cutaneous pyelostomy). The ideal initial treatment is valve ablation with a small Bugbee electrode, as is used with TUI, or the holmium:YAG laser. In small neonates, the 8 or 9 Fr resectoscope may be too large for the urethra, and a temporary vesicostomy may be necessary. A vesicostomy also should be considered for those with a serum creatinine level that remains significantly elevated after bladder decompression. Cutaneous pyelostomy rarely affords better drainage compared with cutaneous vesicostomy and diverts urine away from the bladder, which may prevent normal bladder



(d) (e) (f)

Figure 100.9 (Continued) Newborn with posterior urethral valves and abdominal distension secondary to urinary ascites. **(d)** Voiding cystourethrogram. Note dilated prostatic urethra proximal to the valve leaflets and bladder diverticulum on left side. Patient managed with upper tract drainage and transurethral incision of valve leaflets. **(e, f)** Renal sonogram, left and right kidneys at 6 months of age shows minimal hydronephrosis. At 17 years, patient had nearly normal renal appearance on ultrasound.

growth.[72] However, in selected cases, the Sober-en-T cutaneous ureterostomy is useful. In this procedure, the upper ureter is brought out to the abdomen and transected, and the distal segment is anastomosed to the renal pelvis; this option allows urine to drain both through the ureterostomy and to the bladder.[73]

Vesicoureteral reflux

Some neonates with medium- and high-grade VUR are detected following the finding of ANH. Approximately 80% of such patients are boys. In the most severe cases of massive VUR, the bladder may also become distended from aberrant micturition into the upper urinary tract. In the AUA Reflux Guidelines analysis, reflux-related renal scarring was present in 47.9% of those with grades IV–V VUR, but only 6.2% of those with grades I–II VUR.[32] Consequently, in neonates with grades III–V VUR, a DMSA scan is recommended to determine whether reflux-related renal scarring is present. Initially, neonates with prenatally diagnosed VUR are managed medically. Most are placed on amoxicillin prophylaxis for 2 months, followed by nitrofurantoin or trimethoprim–sulfamethoxazole prophylaxis, and circumcision is recommended for male neonates to decrease the risk for UTIs.

Neonates with VUR are more likely to show spontaneous resolution than are older children. Indeed, 20%–35%

of ureters with grade IV or V VUR have reflux resolution within 2 years; however, a significant proportion develop a breakthrough UTI, and antireflux surgery is recommended in these cases. The success rate for open surgical correction of VUR in infants can be as high as in older children.[56] Another option is subureteral injection of dextranomer microspheres/hyaluronic acid into the ureterovesical junction, in which the success rate is 69% with a single injection.[74]

SUMMARY

Approximately 1%–2% of newborns have an antenatal diagnosis of hydronephrosis or significant renal pelvic dilation. Hydronephrosis is often caused by non-obstructive conditions. The likelihood of significant urologic pathology is directly related to the size of the fetal renal pelvis, and 90% with an APD >2 cm need surgical intervention or long-term urologic follow-up. Following delivery, antibiotic prophylaxis should be administered, and a renal sonogram and VCUG should be obtained. If there is grade 3 or 4 hydronephrosis, a diuretic renogram is usually also recommended. Pediatric urologic or pediatric nephrologic consultation is helpful in planning evaluation and treatment. Antenatal recognition of hydronephrosis allows postnatal diagnosis and treatment of urologic pathology, preventing complications of pyelonephritis and obstruction. In the past decade, significant progress has been made in the development of minimally invasive treatment options.

Multicystic dysplastic kidney

DAVID F. M. THOMAS AND AZAD S. NAJMALDIN

INTRODUCTION

It is now more than 30 years since cases of antenatally detected multicystic dysplastic kidney (MCDK) were first reported in the literature. Before then, MCDK was regarded as a rare anomaly, which generally presented as an abdominal mass in the neonatal period. Nephrectomy was the standard form of management. Over the last three decades, however, it has become apparent that MCDK is, in fact, a relatively common renal anomaly, with a prevalence in the range of 1 in 2500 to 1 in 4000.[1,2] It has also become clear that the majority of MCDKs are small and clinically undetectable and would probably have remained unrecognized throughout the individual's lifetime if they had not been detected on antenatal ultrasonography. The weight of published evidence now supports a conservative approach in the majority of cases, with nephrectomy being reserved for specific indications.

ETIOLOGY

MCDK is almost invariably associated with the presence of an atretic segment in the proximal ureter. Nevertheless, it can occasionally occur in conjunction with ureteral dilatation and an obstructive ureterocele. In both forms, the underlying mechanism is thought to be a severe obstructive insult to the developing metanephric mesenchyme at an early stage in gestation. MCDK is the most common form of cystic renal disease in children. The occurrence of bilateral MCDKs is invariably lethal and, when detected prenatally, usually leads to termination of pregnancy. Unilateral MCDK is generally a sporadic anomaly, but familial occurrence has been described, with an autosomal dominant pattern of inheritance, variable expression, and reduced penetrance.[3] MCDKs are slightly more common in boys, and the left side is affected more frequently than the right. Macroscopically, MCDKs comprise an irregular collection of tense, noncommunicating cysts of different sizes. The histological appearance is characterized by cysts lined by cuboidal or flattened tubular epithelium. Any renal parenchyma is confined to small islands or flattened plates of dysplastic tissue interposed between cysts.

The presence of a solid component of renal parenchyma effectively excludes the diagnosis of MCDK. These variants can create diagnostic confusion. Some of the reported cases of hypertension and malignancy have been incorrectly attributed to MCDKs when they have, in fact, arisen in these variants.[4]

Coexisting urological anomalies are common and include a 20% incidence of Vesico ureteric reflux (VUR) (usually low grade) and a 5% incidence of Pelvi ureteric junction (PUJ) obstruction in the contralateral kidney. Ipsilateral genital abnormalities such as Gartner duct cyst may also be present.

PRESENTATION

Patterns of presentation include the following:

1. Antenatal ultrasound detection (the majority).
2. Clinical presentation. Large multicystic kidneys generally present as a firm, "knobbly" abdominal mass, which is apparent at birth or early in the neonatal period.
3. Incidental finding during the investigation of some unrelated illness.
4. Symptomatic complications (very rare).

INVESTIGATIONS

Ultrasound

The ultrasound features that characterize MCDKs are now widely accepted and well defined in the radiological literature (Figure 101.1).[5–7] Failure to understand or apply these criteria correctly accounts for some of the purported cases of hypertension[4] and malignancy that have been incorrectly ascribed to MCDKs.

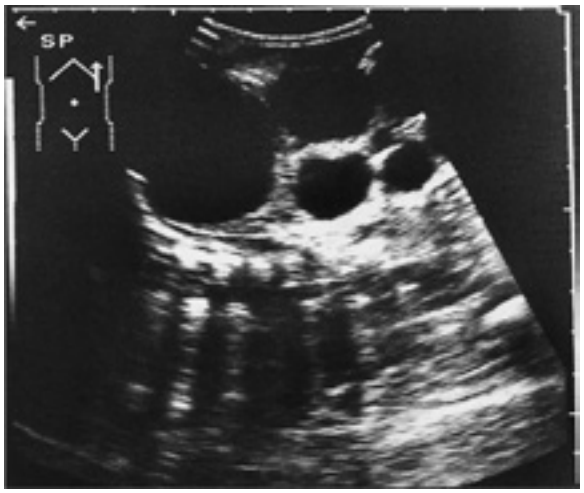

Figure 101.1 Typical ultrasonographic appearance of neonatal multicystic dysplastic kidney, i.e., noncommunicating cysts of varying size, demonstrable septa between cysts, no visible rim or cortical tissue.

The diagnostic criteria on ultrasonography comprise the following:

- Multiple oval or round cysts that do not communicate
- Presence of interfaces between the cysts
- Nonmedial location of the largest cyst (a large fluid-filled component located medially is more likely to represent the dilated pelvis of a severely hydronephrotic kidney)
- Lack of central sinus echo
- Absence of solid parenchymal tissue

When the diagnostic criteria are applied correctly, the sensitivity of ultrasonography for the diagnosis of MCDK is extremely high. Where uncertainty exists, it usually relates to severe hydronephrosis or a solid dysplastic kidney with a cystic component.

Isotope renography (nuclear medicine scan)

It has been argued that the predictive value of ultrasonography is now so high that it is no longer necessary to perform isotope renography to confirm the diagnosis.[7,8] Nevertheless, it remains standard practice in most centers to include isotope renography in the routine evaluation of MCDKs. This is intended to differentiate genuine MCDKs, which are totally nonfunctioning (0% differential function), from grossly hydronephrotic kidneys or other forms of renal dysplasia, which usually have some demonstrable function (albeit only a few percent differential function on technetium-99m dimercaptosuccinic acid [^{99m}Tc-DMSA]). In equivocal cases, nephrectomy is justified to establish a histological diagnosis and to obviate the possible risk of complications, notably hypertension.

^{99m}Tc-DMSA is the most reliable modality for demonstrating low levels of function (Figure 101.2a,b). Nevertheless, technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG3) may be preferable if there is any suggestion of contralateral pelviureteric junction obstruction. Ideally, imaging should be deferred until after the fourth week of life.

Voiding cystourethrography

Opinion is divided on whether it is necessary to perform this invasive investigation routinely if the urinary tract

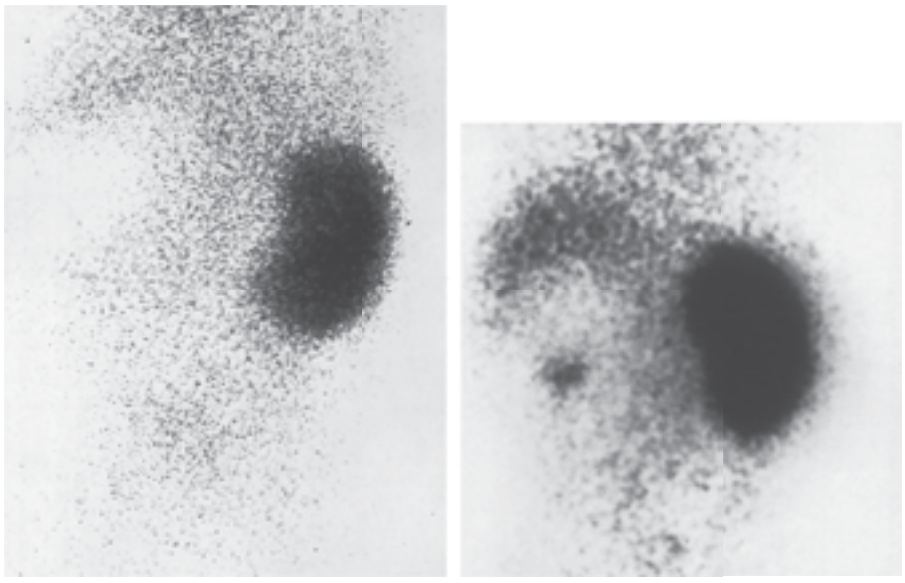

Figure 101.2 **(a)** ^{99m}Tc-DMSA scan demonstrating normal isotope uptake and renal morphology on the left, and no uptake or isotope in the right (multicystic) kidney. **(b)** A focus of poor but discernible uptake of ^{99m}Tc-DMSA in a grossly hydronephrotic right kidney. Ultrasound could not distinguish with certainty between gross hydronephrosis and multicystic kidney.

appears otherwise normal on ultrasound. The findings of several studies have endorsed the safety of omitting a routine voiding cystourethrography (VCUG) in such cases.[9,10] When VUR is present it is usually low grade and self-limiting. Children with MCDK who have not undergone a routine VCUG do not appear to be at any higher risk of urinary tract infection (UTI) or renal damage. However, if a routine VCUG is not performed, it is important that parents and general practitioners are aware that the occurrence of a documented or suspected UTI or an unexplained febrile illness should prompt further investigation to look for possible VUR.

However, VCUG is always indicated when postnatal ultrasonography reveals evidence of ipsilateral ureteric dilatation or contralateral upper tract dilatation.

NATURAL HISTORY OF PRENATALLY DETECTED MCDKS

This is characterized by a process of shrinkage (involution). MCDKs measuring less that 5–6 cm on initial assessment have a high probability of disappearing completely on ultrasound over the first 10 years of life. Those that exceed this figure on initial assessment also demonstrate considerable reduction in size but are less likely to involute completely over this timescale.[11,12] The risk of complications such as hypertension is exceedingly low regardless of initial size, and there is no evidence of any correlation between the risk of complications and initial size. Likewise, MCDKs that do not involute completely do not appear to pose a significantly greater risk than those that do. There is no evidence-based justification for advocating nephrectomy on the basis of either the initial size of the MCDK or the persistence of an MCDK on follow-up ultrasound.

Whereas MCDK is a relatively common antenatally detected anomaly, unilateral renal agenesis is rarely diagnosed *in utero*. This has been interpreted as evidence that a significant proportion of cases of apparent unilateral renal agenesis detected in adults had originated as MCDKs and then undergone complete involution. Regardless of the outcome for the MCDK, the contralateral kidney almost invariably undergoes some degree of compensatory hypertrophy.

INDICATIONS FOR SURGERY

The following are widely regarded as *definite indications for nephrectomy*:

1. *An obvious, visible and readily palpable abdominal mass.* In this situation, there is usually considerable parental anxiety. In addition, there may be apparent discomfort or other symptoms attributable to the size of the mass.
2. *Diagnostic uncertainty.* Despite the combination of ultrasound and isotope imaging, it may occasionally be impossible to distinguish with certainty between an MCDK, a poorly functioning hydronephrotic kidney, and a rare cystic variant of renal dysplasia. The presence of demonstrable function in what otherwise appears to be an MCDK should be viewed with suspicion and represents a valid indication for nephrectomy. Isotope function equates with perfusion, and it can be reasonably argued that perfused tissue imparts a greater risk of renal hypertension. Likewise, a cystic anomaly that is also seen to contain a solid parenchymal component or that does not fulfill the other diagnostic criteria listed previously is *not* an MCDK and is, therefore, best removed.

Controversies surrounding "prophylactic" nephrectomy for asymptomatic, prenatally detected MCDKs

Although the overwhelming majority of prenatally detected MCDKs are asymptomatic and clinically undetectable, some surgeons continue to practice "prophylactic" nephrectomy. They argue that this policy is justified by published reports of complications—notably hypertension and malignant transformation.

Following the introduction of antenatal diagnosis, the assessment of risk associated with MCDKs was initially based on historical case reports. Critical analysis of the historical literature has, however, shed doubt on the accuracy of the diagnosis of MCDK in the historically reported cases. The distinguished pediatric pathologist, Beckwith, observed, "The literature concerning renal tumors in multicystic dysplastic kidney is burdened with poorly documented or unconvincing cases."[13]

It is now no longer necessary to resort to the historical literature since there is now an extensive body of literature that is devoted specifically to antenatally detected MCDKs. A detailed review is beyond the scope of this chapter, but the following summary is intended to provide readers with an evidence-based assessment of the level of risk.

Malignant transformation (Wilms tumor)

Narchi[14,15] undertook a detailed review of 26 published series totaling 1041 children with conservatively managed MCDKs. Information on duration of follow-up was available in 18 publications, and it was between 1.25 and 6.5 years, with a maximum of 23 years. No cases of Wilms tumor were identified in this literature review.

Cambio and associates[16] reviewed 105 publications on prenatally detected MCDK, to which they added unpublished data from the United States recorded in the MCDK registry on approximately 900 MCDKs.[17] From this comprehensive analysis of the literature, these authors identified 3 cases of Wilms tumor arising in a prenatally detected MCDK—none of which occurred after 4 years of age. No cases were reported to have arisen in MCDKs that had involuted. The Trent and Anglia MCDK Study Group systematically collected prospective data on 323 children with

antenatally detected MCDK, with a median duration of follow-up of 10.1 years (0.3–15.4 years). No Wilms tumors were encountered in any of these patients. Similarly, no Wilms tumors occurred in 325 children with prenatally detected MCDKs managed conservatively at Great Ormond Street Hospital. Of these, 180 children with MCDKs had been followed prospectively for more than 10 years (unpublished data, Dhillon H. K., personal communication, 2009).

It could be argued that the published data might underestimate the true incidence of malignancy because not all cases have been reported in the literature. However, the risk of malignancy can also be approached from a different perspective by considering how frequently MCDKs feature in published series of Wilms tumor. This question was addressed by studying data on 7500 Wilms tumors reported to the National Wilms Tumor Study Pathology Center over an 18-year period. Of the 7500 Wilms tumors, 5 had arisen in MCDKs.[13]

On the basis of these data coupled with published data on the prevalence of MCDKs, it was calculated that individual lifetime risk of developing Wilms tumor in an MCDK was approximately 1 in 2000. If anything, this calculation overstates the risk because the overall prevalence of MCDK in the pediatric population is somewhat higher than the figure on which this calculation was based. In summary, the best available data indicate that the risk of developing a Wilms tumor in a prenatally detected MCDK is probably on the order of 1 in 5000.

The risk of hypertension has also been cited to justify the practice of prophylactic nephrectomy. There is now a growing body of evidence with which to quantify the scale of this risk. No cases of hypertension were encountered in 323 children with prenatally detected MCDK followed prospectively for a median of 10.1 years by the Trent and Anglia MCDK Study Group,[12] and no instances of hypertension were recorded in 441 children with prenatally detected MCDKs enrolled in the MCDK registry.[17]

Narchi's[14] literature review did, however, reveal a published incidence of hypertension of 0.5%. However, it is important to recognize that confirming a reliable diagnosis of hypertension in this age group can be problematic because of the difficulties inherent in obtaining accurate, reproducible blood pressure readings in fractious infants and young children.

As with malignancy, the risk of hypertension can also be viewed from a different perspective. MCDK is now known to be a relatively common anomaly with a birth incidence in the range of 1 in 2500 to 1 in 4000.[1,2] If MCDKs were resulting in hypertension on any appreciable scale, it could be expected that they would account for a sizeable proportion of children with hypertension. This is not the case. For example, in a series of 21 children with renal hypertension managed by nephrectomy at Great Ormond Street Hospital between 1968 and 2003, there was only one case of MCDK.[18]

Removing an MCDK may not entirely obviate the risk since there are well-documented cases of hypertension arising in the contralateral kidney.[19] Moreover there is also some evidence that individuals with a solitary kidney are at an increased lifetime risk of developing hypertension.

In summary, the best currently available evidence puts the risk of developing hypertension associated with a prenatally detected MCDK at less than 1% (probably significantly less).

The relative ease and safety with which MCDKs can be removed laparoscopically is sometimes cited as an argument in support of prophylactic nephrectomy. But the technical ease with which an operation can be performed can never be regarded as a legitimate indication in its own right. The overwhelming majority of children with antenatally detected MCDKs are entirely healthy and asymptomatic. There is a growing body of evidence that the scale of risk associated with an antenatally detected MCDK is exceedingly low. In these circumstances, it is important that the surgeon and parents give very careful consideration to the evidence before submitting a healthy, asymptomatic child to surgery and general anesthesia.

Timing of surgery

Large multicystic kidneys associated with a sizeable mass should be removed electively in the first few weeks of life. Smaller lesions for which surgery is nevertheless thought to be appropriate can safely be left until 6–12 months of age or later. It is important to obtain an ultrasound scan shortly before surgery to confirm that the MCDK is still visible and has not undergone involution in the period since the decision was made to operate.

SURGICAL OPTIONS

Nephrectomy for MCDK is now performed laparoscopically (conventional or robot assisted) in most western pediatric surgical centers. However, the open approach is a reasonable alternative if the surgeon lacks the necessary expertise in minimally invasive surgery or suitable pediatric equipment is not available.

Open nephrectomy

Dorsal or posterior lumbotomy has the advantages of simplicity, good cosmesis, reduced postoperative pain, and shortened hospital stay.[20,21] The major drawbacks are the limited access to the kidney afforded by this incision and difficulty in extending it if the surgeon encounters an unforeseen problem. For a small MCDK, the dorsal lumbotomy incision is ideal, and even for larger lesions, nephrectomy should not pose problems, provided that the bulk of the multicystic kidney is reduced by cyst aspiration prior to its removal.

For surgeons unfamiliar with the dorsal lumbotomy incision, the more familiar loin approach is described in detail as follows.

OPERATIVE DETAILS

Position of the patient

A full lateral position is employed (Figure 101.3). Lateral flexion of the spine is best achieved in this age group by the use of a sandbag under the contralateral loin. Once the required position has been achieved, adhesive strapping is used to maintain it. The strapping is fixed first to one side of the operating table, taken across the abdomen at the level of the iliac crests, and then is secured firmly on the other side of the table.

Incision and approach to the kidney

The twelfth rib is identified by palpation. A preoperative plain x-ray is helpful in determining the length of the twelfth rib. Care should be taken to base the incision on the twelfth rib itself (Figure 101.4a), since an inadvertent supra–eleventh rib incision may result in the pleural cavity being opened. After the skin and subcutaneous fat have been incised, cutting diathermy is used to deepen the incision to the tip of the twelfth rib. The muscles attached to the superior border of the twelfth rib (latissimus dorsi, intercostal muscles) are incised along their insertion. The rib is then deflected caudally to allow the surgeon to insert a finger to sweep the peritoneum away from the overlying abdominal wall muscles. The incision can then be extended forward in the line of the rib using the diathermy to divide the external oblique, internal oblique, and transversus abdominis muscles (Figure 101.4b). Care is needed to avoid damaging the neurovascular bundle, as this can result in a visible obvious (but usually self-limiting) postoperative weakness of the relevant segmental abdominal musculature. When the incision has been completed, a self-retaining retractor can be inserted.

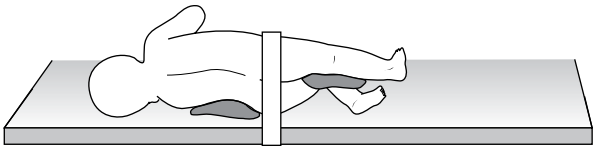

Figure 101.3 Lateral position of the patient.

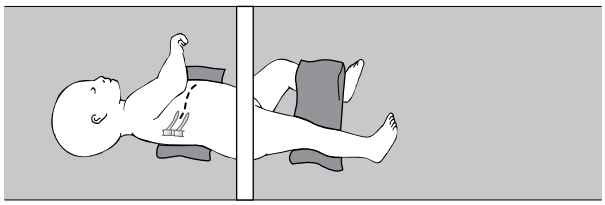
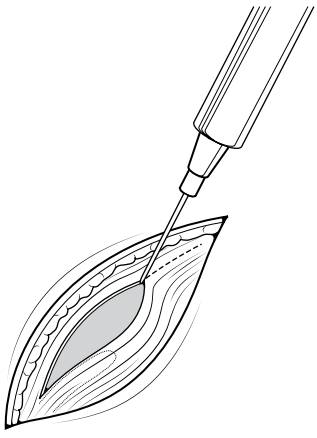


(a)



(b)

Figure 101.4 **(a)** "Supra 12" incision extending medially from the tip of the 12th rib. **(b)** Cutting diathermy used to deepen the incision through the abdominal wall muscles. Peritoneum swept anteriorly with a finger to expose the retroperitoneum.

Mobilization

A small MCDK may initially be difficult to identify within the retroperitoneum. If difficulty is encountered, the dissection is then extended through the retroperitoneal fat and perirenal fat—maintaining close proximity to the posterior abdominal wall to minimize the risk of damage to other viscera. More commonly, the MCDK is identified without difficulty in the renal fossa. A combination of blunt and scissor dissection is used to develop a plane between the cysts and adjacent tissues (Figure 101.5). The peritoneum is usually adherent to an extensive area of the MCDK, and care should be taken to avoid entering the peritoneal cavity. If the peritoneum is incised, the defect should be closed with a continuous absorbable suture.

Once a portion of the kidney has been exposed and mobilized in this fashion, it is helpful to aspirate the visible cysts with a syringe and needle (Figure 101.6). The decompressed cyst wall can then be grasped, e.g., with Allis Tissue Forceps, so that gentle traction can be applied to deliver the kidney out of the incision. By a combination of further dissection around the intact cysts followed by aspiration and mobilization through the incision, it is possible to remove an MCDK through a much smaller incision than would have been required if the cysts were left intact.

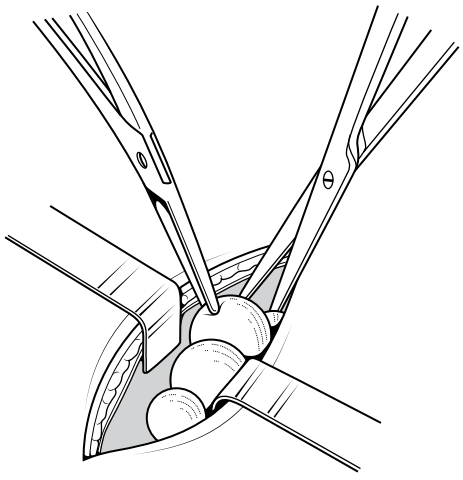


Figure 101.5 Mobilization of the kidney.

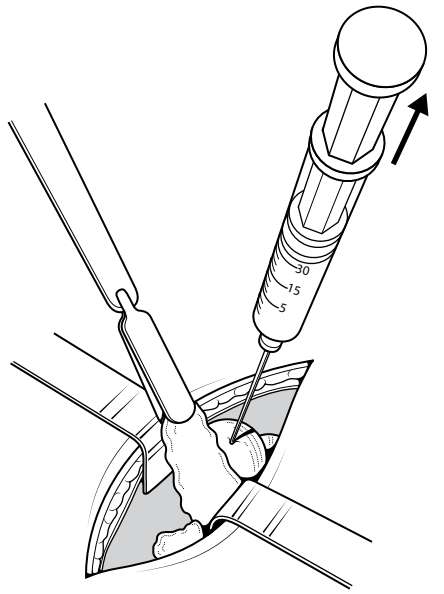

Figure 101.6 Aspiration of cysts.

Dissection of hilum

As the dissection is deepened, a malleable retractor is inserted to retract the peritoneum and expose the ureter and hilar vessels. A vascular sling or tape is placed around the ureter, and gentle traction is applied to facilitate the final dissection of the hilum (Figure 101.7). The ureter is then ligated with 4-0 absorbable suture and divided. Although it is good practice to ligate the renal arteries and veins individually (to prevent the risk of arteriovenous fistula formation), this is often impossible since the vessels are usually small and nonpatent. The renal vessels are ligated in continuity and then divided between the ligatures.

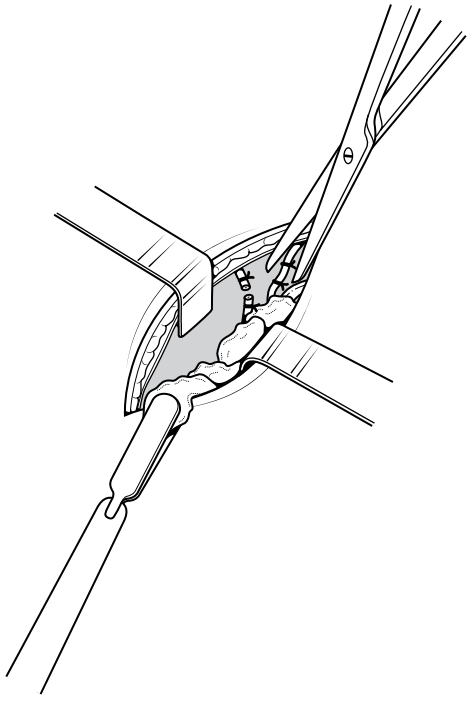

Figure 101.7 Dissection of the hilum.

Removal of the kidney and closure

Once the decompressed MCDK has been fully mobilized, it can be removed following division of any remaining attached tissue.

The renal bed is inspected and diathermy hemostasis performed as required. Similarly, the peritoneum should be checked and any defect closed with a continuous 4-0 absorbable suture. Drainage of the renal fossa is not necessary. This incision is closed either in two layers using a continuous absorbable suture or with a series of interrupted mass sutures encompassing the rib. The skin is then closed with a subcuticular suture of 5-0 Vicryl.

Postoperative care

Postoperative recovery is usually rapid. Feeding is reestablished within 24 hours, and the child can generally leave hospital within 1–2 days.

Laparoscopic nephrectomy

The removal of a normally sited MCDK by laparoscopic or robot-assisted nephrectomy can be performed using either a transperitoneal[22–24] or an extraperitoneal[25] approach. The transperitoneal approach is required for removal of an MCDK located in an ectopic site such as the pelvis.[26]

EQUIPMENT AND INSTRUMENTS

The following are required:

- Camera, light source, insufflator, and one or preferably two monitors with appropriate attachments.
- Diathermy unit (monopolar and bipolar) with appropriate cables and hand probes. Ultrasonic shears, LigaSure, or PlasmaKinetic coagulation devices may be used as an alternative.
- Three or four 2.5–12 mm cannulae and trocars with appropriate converters.
- A 30° or 45°, 2.5–10 mm angled telescope (0° scope may be adequate).
- An appropriate retractor may prove helpful. Often, a simple instrument such as an atraumatic grasper may be used as a retractor.
- Two atraumatic, preferably insulated, relatively fine curved or angled double-action jaw-grasping forceps (an additional forceps with ratchet can be useful).
- One insulated, curved double-action jaw scissors with appropriate diathermy lead.
- Suction/irrigation apparatus and probe.
- A single-load or multiload automatic clip applicator and clips (alternatively, suture ligatures, ultrasound shears, LigaSure, or PlasmaKinetic may be used).
- One long needle to compress cysts if necessary.
- A balloon dissector may be required for extraperitoneal approach.

The size and length of instruments depend on the size of patient, surgeon's preference, and availability of instruments. In addition to laparoscopic equipment, a set of the instruments required for open nephrectomy should always be available in case of emergency or if it becomes necessary to convert to an open approach.

PREPARATION AND POSITION OF THE PATIENT

The procedure is performed under general anesthesia with endotracheal intubation and muscle relaxants. A nasogastric tube is positioned, and a catheter should be passed to drain the bladder if it is palpable and cannot be expressed manually. The infant is placed and strapped securely in the semilateral position with soft towels under the contralateral loin/lower chest to permit lateral flexion and allow the intestine to fall medially under gravity (Figure 101.8).

TECHNIQUE FOR TRANSPERITONEAL NEPHRECTOMY

The theater layout, position of the surgeons, and placement of the cannulae are illustrated in Figure 101.8. The primary cannula is placed in the periumbilical region using an open technique.[27] A pneumoperitoneum is created with CO_2 insufflation through the primary cannula at a flow rate of 0.2–1 L/min and pressure of 8–10 mm mercury.[28] A telescope is then placed through the cannula, and under direct vision, the working cannulae are placed in the direction of the kidney. The sites and sizes of the working "secondary" cannulae are dependent on the size of the patient, the size of the instruments to be used, and the surgeons' preference.[29] The use of two 2.5–5 mm working cannulae in addition to the primary cannula will often provide adequate access for the removal of a MCDK. An additional cannula may be placed for retraction if necessary. An incision in the peritoneum of a few centimeters in length lateral to the upper border of the colon and directly over the lower part of the kidney will allow adequate exposure.[22] Formal mobilization of the colon is not usually necessary in children. The MCDK is then mobilized by blunt and sharp dissection, with traction on the cysts when necessary to facilitate exposure (Figure 101.9). The renal vessels, which are usually attenuated, are exposed in the region of the kidney and divided between clips or ligatures. Other techniques for securing the blood vessels include unipolar or bipolar diathermy, ultrasound shears, LigaSure, or PlasmaKinetic. The ureter distal to the atretic segment is clipped or ligated and divided at a convenient level. If necessary, the bulk of the MCDK can be reduced by needle aspiration prior to removal of the specimen via the largest cannula or site of a cannula with or without 1–2 cm extension. A retrieval bag is usually difficult to accommodate in infants and is not usually necessary. A change of telescope and/or instruments from one cannula to another may serve to facilitate viewing and dissection during the procedure.[29] Postoperative drainage is not necessary. In infants, cannula sites greater than 2.5 mm are closed with absorbable sutures. The opening

Note how a few-centimeters-long high paracolic peritoneal incision directly over the cystic kidney without colon mobilization allows full mobilization of the specimen and hemostasis.

in the peritoneum is covered with colon while the child is being returned to the supine position at the end of the procedure. This maneuver helps to ensure that very little, if any, raw surface is exposed that might promote adhesion formation.

In robot-assisted laparoscopic nephrectomy, position of the patient and ports and the technique are similar to that of conventional laparoscopy. However, the entire procedure can be accomplished using two instruments: an atraumatic and a PlasmaKinetic grasping forceps.[23]

POSTOPERATIVE CARE

The nasogastric tube and (if used) the urinary catheter are removed on the completion of the procedure. Local infiltration of the cannulae sites with an appropriate anesthetic agent provides generally adequate pain relief. Opiate analgesia is not usually required, but intravenous paracetamol may be administered in the early postoperative period as required. Children can usually be discharged from the hospital within 8–24 hours.

Extraperitoneal laparoscopic nephrectomy

Although challenging in infants and small children, this approach is becoming increasingly fashionable. The technique entails creating a space around the MCDK by disrupting up the loose connective tissue in the retroperitoneal plane. This is achieved either with the tip of the telescope and direct CO_2 insufflation or by the use of a balloon dissector.[25,30] This technique avoids the morbidity that may be associated with traversing the peritoneal cavity. However, it has the drawback of more restricted exposure of the kidney. In addition, it carries a risk of tearing the peritoneum, leading to an extension pneumoperitoneum and consequent difficulty in maintaining an extraperitoneal technique. The use of a single-incision retroperitoneal technique has been reported.[31] However any benefits are likely to be minimal and outweighed by the considerable technical limitations imposed by this technique. In general, the extraperitoneal approach does not appear to confer any advantage over the transperitoneal in terms of clinical outcome.[32]

FOLLOW-UP

This is determined by the nature of any coexistent abnormalities. In an otherwise normal child who has undergone nephrectomy for an MCDK, follow-up can be limited to one ultrasound scan at 6–12 months. Thereafter, it is prudent to perform an occasional precautionary ultrasound scan of the solitary remaining kidney until the child reaches an age when he or she could be expected to describe his or her symptoms in the unlikely event of development of symptomatic pathology (e.g., PUJ obstruction) in the remaining kidney. Lifelong annual blood pressure measurement is probably advisable for any individual with a solitary kidney.

Upper urinary tract obstructions

PREM PURI AND BORIS CHERTIN

INTRODUCTION

With the widespread use of maternal ultrasound, the incidence of prenatally detected hydronephrosis has increased significantly altering the practice of urology. The recent review of the trends in the prenatal sonography use and subsequent urological diagnoses in United States demonstrated significant increase in the overall ultrasound use in the last two decades. Moreover, the mean number of ultrasounds per pregnancy also increased significantly from 2.7 in 1998 to 4.2 in 2005.[1] Depending on diagnostic criteria and gestation, the prevalence of prenatally detected hydronephrosis ranges from 0.6% to 5.4%. The condition is bilateral in 17%–54%, and additional abnormalities are occasionally associated. The outcome of prenatally detected hydronephrosis depends on the underlying etiology. Although prenatally detected hydronephrosis resolves by birth or during infancy in 41%–88% patients, urological abnormalities requiring intervention are identified in 4.1%–15.4% and rates of vesicoureteric reflux (VUR) and urinary tract infections (UTIs) are several-fold higher. Pelviureteric junction (PUJ) obstruction is the most common cause of hydronephrosis detected antenatally.[2,3] The next most common cause of prenatally detected hydronephrosis is obstruction at the ureterovesical junction.[2] Management of these patients after birth remains controversial. The decision to intervene surgically in these infants has become more complex because spontaneous resolution of antenatal and neonatal upper urinary tract dilatations is being increasingly recognized.[2,4–6] The recognition and relief of significant obstruction is important to prevent irreversible damage to the kidneys.[7] Differentiating urinary tract dilatations that are significantly obstructive and require surgery from those that represent mere anatomical variants with no implications for renal function is not a simple task especially in the newborns. It has been shown that the changes in the function of the involved kidney should be used as a measure of degree of obstruction and indication for surgical intervention.[4,5,7–10]

PUJ OBSTRUCTION

The overall incidence of PUJ obstruction approximates 1 in 1500 births. The ratio of males to females is 2:1 in the neonatal period, with left-sided lesions occurring in 60%. In the newborn period, a unilateral process is most common, but bilateral PUJ obstruction was found in 10%–49% of neonates in some reported series.[7] PUJ obstruction is classified as intrinsic, extrinsic, or secondary.

Intrinsic obstruction results from failure of transmission of the peristaltic waves across the PUJ with failure of urine to be propulsed from the renal pelvis into the ureter, which results in multiple ineffective peristaltic waves that eventually causes hydronephrosis by incompletely emptying the pelvic contents.[8–11] Tainio et al.[12] have shown the abnormalities of peptidergic innervation with dense innervation of neuropeptide Y and vasoactive intestinal polypeptide, and proposed that these may have a role in intrinsic obstruction. Absence or reduction of smooth muscle with replacement by collagen fibers has been demonstrated histologically.[13,14] Some researchers proposed that downregulation of Cajal cells is responsible for the development of PUJ obstruction.[15] Extrinsic mechanical factors include aberrant renal vessels, bands, adventitial tissues, and adhesions that cause angulation, kinking, or compression of the PUJ. Extrinsic obstruction may occur alone but usually coexists with intrinsic ureteropelvic junction pathology. Secondary PUJ obstruction may develop as a consequence of severe VUR in which a tortuous ureter may kink proximately.[16] Previous reports have described VUR in 9%–15% of children who have PUJ obstruction, although the fractions that are secondary to reflux are difficult to determine.[9,16]

Prenatal diagnosis

The bladder is visualized by 14 weeks of gestation. The presence of full bladder provides evidence of renal function. The ureters are usually not seen in the absence of distal obstruction or reflux. The fetal kidney may be visualized at the

same time as bladder. If not, they are always visualized by 16th week of gestation. However, it is not until 20–24 weeks of gestation, when the fetal kidney is surrounded by fat, that the internal renal structures appear distinct.[16] Renal growth can then be assessed easily.[17] Beyond 20 weeks, fetal urine production is the main source of amniotic fluid. Therefore, major abnormalities of the urinary tract may result in oligohydramnios.

Because of the distinct urine tissue interface, hydronephrosis can be detected as early as 16 weeks of gestation. An obstructive anomaly is recognized by demonstrating dilated renal calyces and pelvis. A multitude of measurement and different gestational age cutoff points have been recommended in the assessment of fetal obstructive uropathy.[18–22] Routine estimation of anteroposterior (AP) diameter of renal pelvis in fetus with hydronephrosis is considered as a useful marker for classification of renal dilatation and possible obstruction. AP renal pelvis threshold values ranged between 2.3 and 10 mm. Positive predictive values for pathological dilatation confirmed in the neonate ranged between 2.3% and >40% for AP renal measurements of 2–3 and 10 mm, respectively. A study that included more than 46,000 screening patients published the standards regarding renal pelvic measurement.[17] This study clearly demonstrated that only fetuses exhibiting third-trimester AP renal pelvis dilatations >10 mm would merit postnatal assessment. In order to standardize postnatal evolution of prenatal hydronephrosis, a grading system of postnatal hydronephrosis was implemented in 1993 by the Society for Fetal Urology (SFU).[23] In SFU system, the status of calices is paramount while the size of the pelvis is less important. In SFU grading of hydronephrosis, there is no hydronephrosis in grade 0. At grade 1, the renal pelvis is only visualized. Grade 2 of hydronephrosis is diagnosed when a few (but not all) renal calices are identified in addition to the renal pelvis. Grade 3 hydronephrosis requires that virtually all calices are depicted. Grade 4 hydronephrotic kidneys will exhibit similar calyceal status with the involved kidney exhibiting parenchymal thinning. Often this classification is applied also on prenatal hydronephrosis. We have recently published our data regarding prenatal findings with the special emphasis on the natural history of hydronephrosis during postnatal period.[7] Our data show that SFU grade of prenatal hydronephrosis is not a significant predictive factor for surgery in unilateral hydronephrosis. However, SFU grade 3–4 prenatal bilateral hydronephrosis indicates that the majority of the children will require surgical correction during postnatal period.

In case of severe prenatal bilateral hydronephrosis, severe hydroureteronephrosis or severe impairment of the solitary kidney fetal bladder aspiration for urinary proteins and electrolytes may be used in order to predict the renal injury secondary to obstructive uropathy. Fetal urinary sodium level of less than 100 mMol/L, chloride level of less than 90 mMol/L and an osmolality of less than 210 mOsm/kg are considered prognostic features for good renal function.

Clinical presentation

The clinical presentation of PUJ obstruction has dramatically changed since the advent of maternal ultrasonographic screening.[3–7] Before the routine fetal ultrasonography, the commonest presentation was with abdominal flank mass. Fifty percent abdominal masses in newborns are of renal origin with 40% being secondary to PUJ obstruction. Some patients present with UTI. Other clinical presentations include irritability, vomiting, and failure to thrive. Between 10% and 35% of PUJ obstructions are bilateral, and associated abnormalities of urinary tract are seen in about 30%.[23] PUJ problems are often associated with other congenital anomalies, including imperforated anus, contralateral dysplastic kidney, congenital heart disease, VATER syndrome, and esophageal atresia. In patients with such an established diagnosis, a renal ultrasound examination should be performed.[24] Although the majority of cases occur sporadically, familial cases have been reported. Hereditary pelviureteric obstruction, which is an autosomal dominant trait with variable penetrance, was suggested, and Izquierdo et al.[25] proposed one of the loci to short arm of chromosome 6 as responsible for the development of PUJ obstruction. Moreover, the importance of angiotensin II and its type 2 receptor (AT2) in the development of congenital urinary tract abnormalities has begun to be appreciated.[24–26] Nishimura et al.[27] reported an association of polymorphism of intron 1 of the AT2 gene (the A-1332G transition, which perturbed AT2 mRNA splicing) in patients with multicystic dysplastic kidneys and/or PUJ obstruction.

Diagnosis

With the increasing number of cases of antenatally diagnosed hydronephrosis, it is difficult to interpret the underlying pathology and its significance. Severe obstructive uropathies are detrimental to renal function. However, on the other hand, hydronephrosis without ureteral or lower tract anomaly is common. The important aspect of postnatal investigations is to identify the group of patients who will benefit from early intervention and those who need to be carefully followed up.

Ultrasound

Follow-up ultrasound examination is necessary in postnatal period in antenatally detected hydronephrosis. If the bilateral hydronephrosis is diagnosed in utero in a male infant, postnatal evaluation should be carried out within 24 hours primarily because of the possibility of posterior urethral valves. If the ultrasound scan is negative in the first 24–48 hours in any patients with unilateral or bilateral hydronephrosis, a repeat scan should be performed after 5–10 days, recognizing that neonatal physiological dehydration may mask a moderately obstructive lesion.

If hydronephrosis is confirmed on the postnatal scan, further careful scan of the kidney, ureter, bladder, and the posterior urethra in boys is essential. Ultrasonography depicts the dilated calyces as multiple intercommunicating cystic spaces of fairly uniform size that lead into a larger cystic structure at the hilum, representing the dilated renal pelvis (Figure 102.1a). Peripheral to the dilated calyces, the renal parenchyma is usually thinned with normal or increased echogenicity.

In order to standardize postnatal evolution of prenatal hydronephrosis, the aforementioned SFU grading system of postnatal hydronephrosis is utilized.

Typically, the ureter is of normal caliber and not seen.[22] But if it is dilated, the size of the ureter is also assessed ultrasonographically and graded 1–3 according to ureteral width <7, 7–10, and >10 mm, respectively.

Radionuclide scans

Diuretic renograms using 99mTc DTPA augmented with furosemide were useful in the diagnosis of urinary tract obstructions for a long time.[28,29] DTPA is completely filtered by the kidneys, with a maximum concentration of 5% being reached in 5 minutes, falling to 2% at 15 minutes. However, in the last decade, it has been reported that use of the tracers that rely on tubular extraction such as 123 I-Hippuran and 99Tc MAG3 (Figure 102.1b) may improve diagnostic accuracy.[30–32] The kidney of the young infant is immature; renal clearance, even when corrected for body surface, progressively increases until approximately 2 years of age. Therefore, the renal uptake of the tracer is particularly low in infants, and there is a high background activity. Thus, traces such as123 I-Hippuran and 99Tc MAG3 with a high

(Lt arrow shows PUJ obstruction on the left side. Rt arrow shows normal renal pelvis.)

extraction rate provide reasonable images enabling estimation of the differential kidney function during the first few weeks of life. It is also helpful in assessing the size, shape, location, and function of the kidney. Diuretic augmented renogram is a provocative test and is intended to demonstrate or exclude obstructive hydronephrosis by stressing an upper urinary tract with a high urine flow. Obstruction usually is defined as a failure of tracer washout after diuretic stimulation. If unequivocal, it eliminates the need for further investigations. In equivocal cases, F15, in which furosemide is given 15 minutes after injection of the radionuclide trace, provides a better assessment of the drainage of the upper urinary tract. Forced hydration prior to scan increases the predictive value of nonobstructed pattern up to 94%.[31] Since glomerular filtration and glomerular blood flow are still low in the newborn, the handling of isotype is unpredictable and can be misleading. Koff et al.[32] therefore feel that the risk of making a misdiagnosis of obstruction in this age group far outweighs the potential damage to renal function that might result from delaying surgery for a few weeks until the diagnosis can be made more accurately. Therefore, the timing of the performance of radionuclide studies is of crucial importance.

In those cases where DTPA is used as an isotype, radionuclide study should be postponed until 6–8 weeks after birth allowing kidney to multiply the number of the functioning glomeruli. When 99Tc MAG3 is utilized in the diagnosis of the obstruction, the radionuclide study may be performed as early as 2 weeks of age in those cases where prompt diagnosis is required.

Diagnosis of PUJ obstruction can be made by intravenous urography. Although this investigation shows a dilated renal pelvis with clubbed calyces, it is often not helpful as the concentration of contrast is unreliable and, nowadays, it has no place in the diagnostic armamentarium (Figure 102.1c).

Recently, the value of the new tool named magnetic resonance urography (MRU) has begun to be appreciated in the diagnosis of upper tract obstructions.[33,34] The advent has facilitated the assessment of both function and morphology of the urinary tract, increasing therefore the accuracy of diagnostic workup. The advantages of this relatively new modality reside not only in the nonuse of ionizing radiation but also especially in the acquisition of images with higher contrast and spatial resolution in any orthogonal plane compared with conventional techniques. Certain pathological conditions, such as neoplasms, infections, parenchymal ischemias, and hemorrhage, as well as obstructions and anomalies, can be accurately identified. The addition of new rapid magnetic resonance imaging techniques with high temporal resolution has allowed quantification of corticomedullary perfusion along with the renal excretory function (Figure 102.1d).[34]

PRESSURE-FLOW STUDY

In the equivocal cases and in the presence of impaired function, the pressure flow study (Whitaker test) and antegrade pyelography may be necessary to confirm or exclude obstruction.[35] Whitaker test is based on the hypothesis that if the dilated upper urinary tract can transport 10 mL/min without an inordinate increase in pressure, the hydrostatic pressure under physiological conditions should not cause impairment of renal function, and the degree of obstruction, if present, is insignificant. However, it is an invasive test and is seldom required. Antegrade pyelography may be performed with ultrasound guidance in patients where diagnosis is difficult.[36] Retrograde pyelography is seldom required to determine the status of ureters. The disadvantages include difficulty in ureteral catheterization in neonates, and trauma and edema may change partial obstruction to a complete one. In patients where diagnosis is equivocal, serial examinations may be necessary.

Treatment

Considerable controversy exists regarding the management of newborn urinary tract obstructions. Some authors advocate early surgical intervention to prevent damage to maturing nephrons,[37] while others feel that early surgery carries no specific benefit.[4–7] During late prenatal and early postnatal life, there is progressive increase in the glomerular filtration rate.[5] Additionally, this transition is associated with an abrupt decline in urine output from what appears to be a quite high in utero output to a rather low early neonatal level of urine production. These physiological observations may explain the common observation of hydronephrosis detected antenatally, which on postnatal follow-up reverts to an unobstructed pattern.[1,5,10] In 1990, in a pioneering manuscript, Ransley et al.[4] reported the results of nonoperative treatment in newborns with nonrefluxing hydronephrosis and differential renal function >40%. At 6-year follow-up, only 23% needed surgical correction. The most common indication for surgery in this group of children was deterioration of renal function. Subsequently, Koff and Cambell[5] reported that out of 104 neonates with prenatally diagnosed unilateral hydronephrosis who have been followed conservatively, only 7% required pyeloplasty in long-term follow-up. Furthermore, the same group reported results of initial conservative management of children with severe unilateral hydronephrosis due to PUJ obstruction.[39] Only 22% of these children required pyeloplasty. All children who required surgery were younger than 18 months and had progressive hydronephrosis and/or reduction in renal function. Therefore, immediate postnatal surgical intervention is unnecessary in the majority of newborn children with PUJ obstruction. These babies should be followed up with serial examinations to observe anatomical and functional improvement. Surgery is undertaken in infants with deteriorating renal function.[3–5,7,38–40] We have reported our experience of over 16 years (1988–2003) with 343 children (260 males and 83 females) with antenatal diagnosis of hydronephrosis, which led to postnatal diagnosis of PUJ obstruction, who were followed conservatively. Of the 343 children, 110 had

right-sided hydronephrosis and 233 had left-sided hydronephrosis. According to SFU classification, none had grade 0 of postnatal hydronephrosis, 20 had grade 1, 118 grade 2, 147 grade 3, and the remaining 58 children had grade 4 postnatal hydronephrosis. Relative renal function (RRF) on radionuclide scans revealed 235 children with RRF more than 40%, 68 with RRF between 30% and 40%, and 40 patients with RRF less than 30%. Renal function deterioration of more than 5% served as a main indication for surgery.[7] We have founded that 179 (52.2%) children required surgical correction in the course of conservative management. The average age at surgery was 10.6 months (range of 1 month to 7 years). Of those, 50% underwent surgery during the first 2 years of life, and majority of the remaining patients underwent surgery between the second and fourth years of age; only two patients required surgery later on. Univariate analysis revealed that child sex, side of hydronephrosis, and SFU grade of prenatal hydronephrosis are not significant predictive factors for surgery. However, SFU grade 3–4 of postnatal hydronephrosis and RRF less than 40% were significant independent risk factors that led to the surgical correction.

Pyeloplasty

Pathological variations in PUJ obstruction necessitate the surgeon to be conversant with the various techniques of the pyeloplasty.[41–47] The objective of the pyeloplasty is to achieve dependent, adequate calibered watertight PUJ. There are different approaches for open pyeloplasty. The classic traditional approach is an extraperitoneal one via lateral flank incision. The infant is placed on the operating table in a supine position with the affected side elevated on a roll (Figure 102.2a). Muscles are either cut or split (Figure 102.2b–d). Gerota's fascia is opened (Figure 102.2e). In the past, it was recommended to pass an appropriate-size silicone tube from opened PUJ down the ureter to the bladder in order to check for distal obstruction. However, we have abandoned this approach due to the possibility of the development of subsequent ureterovesical junction (UVJ) obstruction as a result of the injury to the fragile UVJ area from the passing catheter. The current diagnostic modalities almost certainly exclude existence of any double pathology. In those cases where suspicion to the distal to PUJ area has arisen, antegrade or retrograde study of the ureter upon or during surgery is recommended.

In some cases, the posterior lumbotomy may be applied.[41,42] The use of muscle splitting rather than muscle cutting makes it almost a minimally invasive procedure. The location of the incision just under and parallel to the 12th rib has a cosmetic advantage. The bilateral procedure is possible if indicated under the same anesthesia without changing position. This approach should not be used in older children or those who are significantly obese.

The various techniques of pyeloplasty are divided into dismembered and nondismembered pyeloplasty.

DISMEMBERED PYELOPLASTY

Anderson–Hynes pyeloplasty

The renal pelvis, PUJ, and proximal ureter are freed of perirenal fat. Three stay sutures are placed: (1) at the superomedial aspect of the pelvis, (2) at the inferolateral aspect of the pelvis, and (3) on the ureter about 5 mm below PUJ. The ureter is divided obliquely above the ureteric stitch and the redundant pelvis trimmed (Figure 102.3a). The superior two-thirds of the pelvis is closed by using continuous 6/0 maxon stitch (Figure 102.3b). An oval-shaped anastomosis between the ureter and the lower part of the pelvis is carried out from the posterior to the anterior layer over a silastic stent using 6/0 maxon continuous stitch (Figure 102.3c and d). After the anastomosis is completed, a Redivac drain is placed. Gerota's fascia is closed with interrupted 3/0 chromic catgut sutures. Muscles are approximated in layers and skin by using subcuticular 5/0 Dexon. We have utilized a Pippi–Salle stent nephrostomy tube (Cook, USA) for dismembered pyeloplasty. In order to avoid passing of the distal end of the Pippi–Salle stent nephrostomy through the UVJ in the small children, we cut the distal tail of the tube and leave a distal end in the ureter below the anastomosis. The proximal end of the stent is positioned in the renal pelvis. The nephrostomy end is opened for the drainage for the

next 48–72 hours after surgery. After that, the nephrostomy is clamed and the patient is discharged home following removal of the drain. The tube is removed in the office usually 4 weeks after surgery.

NONDISMEMBERED PYELOPLASTY

The Y plasty (Foley)

This is based on the principle of a Y–V flap. This operation is suitable when the ureter is inserted high on the pelvis. V-shaped incision is made on the pelvis on the anterior and posterior surface. The tail of the incision is on the lateral surface of the ureter well below the obstruction. The flap of the pelvis is brought down, and posterior and anterior anastomosis of the flap and the ureter was performed using 6/0 maxon.

The spiral flap (Culp)

The spiral flap (culp) is suitable for long, dependent, stenotic ureteropelvic obstruction. The incision on the ureter must be adequate covering the stenotic area. A flap of equal length is based on a broad base (Figure 102.4a). The posterior layer of the ureter and the flap is sutured using 6/0 maxon (Figure 102.4b). The anterior layer is crossed over the stent and anastomosed using 6/0 maxon (Figure 102.4c).

The endoscopic technique has gained some popularity in the surgical treatment of PUJ obstruction.

Endopyelotomy

Endopyelotomy can be done by utilizing either percutaneous antegrade approach or endoscopic retrograde procedure.[43] Even strong and experienced surgeons do not recommend to do this procedure in neonates, infants, or young children.[44] Percutaneous endopyelotomy is performed by making an incision on the posterolateral wall using a smaller endoscope and using a 3F or 5F electrocautery probe, and followed by separating the cut edges using a balloon. A ureteral stent is placed for drainage for 6 weeks and nephrostomy tube for 3 days to 6 weeks. Kavoussi et al.[45] have shown that this procedure is also safe and effective in treating secondary PUJ obstruction.

Figenshau and Clayman[46] used a retrograde technique for old children and combined antegrade–retrograde for young children. The incision in the PUJ segment was done using an Acucise balloon with fluoroscopic control. They concluded that the technique has an 86% successful rate and should be offered to pediatric patients with PUJ obstruction. Balloon dilatation of PUJ has also been reported in infants and young children. This consists of dilatation of the PUJ segment using a dilating balloon catheter (12–24 Fr), which

is positioned, confirmed, and inflated for 3 minutes under fluoroscopic control. The success rate has been reported as 63% with follow-up of up to 23 months.

LAPAROSCOPIC PYELOPLASTY

Laparoscopic Anderson–Hynes dismembered pyeloplasty has recently gained wide popularity in pediatric population.[47–49] A decade ago, Yeung et al.[48] reported the results of initial experience with retroperitoneal dismembered pyeloplasty in 13 infants and children. The authors concluded that laparoscopic Anderson–Hynes dismembered pyeloplasty is feasible and safe in infants, but stressed that the long-term results are awaited in order to prove that this method is durable in the long term in children. Since then, the visibility of the laparoscopic approach has found support in numerous publications.[49] Surgery may be performed through either retroperitoneal or transperitoneal approaches. The retroperitoneal approach is safe but technically more demanding due to the smaller operative space and additional difficulties in facilitating intracorporeal suturing. Moreover, it is more difficult to teach residents to perform laparoscopic surgery while utilizing the retroperitoneal approach. In order to facilitate laparoscopic pyeloplasty, some technical steps may be employed. Utilizing a transperitoneal approach allows increasing an operative space especially in small children. Laparoscopic pyeloplasty on the left side may be performed through the transmesenteric approach. The placement of the stay suture on the renal pelvis prior to suturing the anastomosis between renal pelvis and the ureter stabilizes the suture line and allows precise sutures placement, therefore eliminating the risk of reobstruction. Beyond the complexity imposed by the intracorporeal suturing, the presence of a ureteral stent (previously placed by cystoscopy) in front of the anastomotic site makes the suture even more difficult and time-consuming. The retrograde cystoscopic and the antegrade laparoscopic approaches are currently the two options for stent insertion during laparoscopic pyeloplasty. We have recently published our novel technique of stent placement during laparoscopic pyeloplasty. Following identification and dissection of the PUJ with the proximal part of the ureter, the ureter is dismembered just proximal to the PUJ at the level of the renal pelvis, allowing use of the excess pelvic tissue for further manipulation of the ureter. Then the abdomen is desufflated and the ureter delivered to the skin level. The externalized ureter is then spatulated and the stent inserted in an antegrade fashion to the bladder. The first stitch for further laparoscopic anastomosis is applied to the lower part of the spatulated ureteric end, and then following insufflations, the ureter is returned to the abdomen. The laparoscopic anastomosis is completed in a routine fashion.[50]

The final development in the laparoscopic reconstructive surgery in children was the employment of robot-assisted surgery. Robotic technology is changing the way surgery is performed.[51] It allows in situ surgery as well as increased magnification and dexterity for minimally invasive surgery. The development and application of pediatric robotic urology are currently manifesting themselves with rapid growth. The currently available system (DaVinci, Intuitive Surgical, Sunnyvale, CA) is a robotic manipulative device that permits a surgeon to have better control over the instruments. The impression with robot-assisted surgery is that the suturing is easier, and less operating time is required to perform laparoscopic pyeloplasty. Furthermore, it is much easier to teach a surgeon without prior laparoscopic experience to perform laparoscopic pyeloplasty while using a robot-assisted suturing technique.[52] As with laparoscopic pyeloplasty, robot-assisted pyeloplasty can be performed by a trans- or retroperitoneal approach. Suturing is done with a 6-0 monofilament absorbable suture, but one can utilize any 5-0 or 6-0 suture depending on the size of the patient. Currently, it appears that nothing larger than 6-0 for small children and infants is recommended. Robot-assisted pyeloplasty in children has been demonstrated to be feasible and to have satisfactory results. Although there are only a few published series on the long-term outcome to date, the short-term data suggest that outcomes are similar to those of open pyeloplasty in children, and it appears to be more than promising.

Recently available on the market, the da Vinci XI model allows easier docking of the system, allows more convenient manipulation in the pediatric population, and significantly decreases the operation time. However, still the high initial cost of robotic equipment and expensive maintenance of the working system cannot be ignored.

NEPHRECTOMY

Because the recovery potential of the kidney is greater in neonates, extreme conservation is justified. Salvage pyeloplasty should be considered as renal function shown on renal scintigraphy can recover.[53] At operation, an assessment should be made of the renal cortex after emptying the pelvis. Severe cystic dysplasia is an indication for nephrectomy; otherwise, every effort should be made to salvage the kidney.

BILATERAL PELVIURETERIC OBSTRUCTION

Surgical correction of the symptomatic side or the side with better function should take precedence. If a nephrectomy is considered on one side, the pyeloplasty should precede this.

Postoperative complications

Postoperative complications include infection, adhesive obstruction (transperitoneal approach), temporary obstruction at the anastomosis resulting in excessive urine leakage, and failure due to postoperative stricture at anastomotic sites. An overall reoperation rate of 8.2% was reported in the early series.[44] However, when temporally double-J stents or stent nephrostomy tube were utilized, the reoperation rate was negligible.

Follow-up and results

Follow-up ultrasound may be performed 3–6 months after operation when maximum improvement can be seen.[7] Radionuclide scans are useful to monitor the postpyeloplasty

function and drainage. Pyeloplasty in the neonatal period, when indicated, gives excellent results. We have evaluated whether improved renal function after pyeloplasty for prenatal ureteropelvic junction obstruction persisted through puberty.[54] Out of more than 600 patients who underwent successful pyeloplasty and demonstrated an improvement of the renal function following surgery, 49 patients who completed puberty demonstrated that the renal function remained stable during and after puberty.

MEGAURETER

Megaureter is a ureter that is dilated out of proportion to the rest of the urinary tract and above the norms. Cussen[55] and, later, Hellstrom et al.[56] have established the normal measurement of the ureteral diameter in infants and children from 30 weeks of gestation to 12 years of age. Normal ureteral diameter in children is rarely greater than 5 mm, and ureters larger than 7 mm can be considered megaureters.

Classification

The Paediatric Urology Society in 1976[57] adopted a standard nomenclature for categorizing megaureters, which is a useful guide for management. There are three types described:

1. Refluxing ureter, which may be primary or secondary to distal obstruction or pathology
2. Obstructive ureter, which may be primary and includes intrinsic obstruction, or secondary due to distal obstruction or extrinsic causes
3. Nonrefluxing, nonobstructed ureter, which may be primary–idiopathic type or secondary to diabetes insipidus or infection

In 1980, King[58] subsequently modified this classification by adding a fourth group consisting of the refluxing, obstructed megaureters.

URETEROVESICAL JUNCTION OBSTRUCTION

The presence of an adynamic distal ureteral segment is the most common cause of a primary obstructive megaureter. The presence of narrowed terminal portion of a ureter will not convey the peristaltic wave or dilate enough to permit free passage of urine. This results in excess boluses of urine, which coalesce and cause ureteral dilatation. The contraction waves become smaller and are unable to coapt the walls of dilated ureters. This, along with infection, could damage the renal parenchyma. The proposed etiologies include the following:

1. Alteration in muscular orientation: Tanagho[59,60] noted in fetal lamb that the muscle coats of the distal ureter develop last and that late arrest in the development results in absence of longitudinally oriented musculature that conducts the peristaltic wave. This results in hypertrophy of the circular fibers causing obstruction.
2. Muscular hypoplasia with fibrosis: McLaughlin et al.[61] found that 69% of narrowed terminal ureteric segments showed muscular hypoplasia, which were separated by fibrotic sheets, thus affecting the transmission of peristalsis. This fibrotic ring prevents expansion and free urinary drainage.
3. Excessive collagen deposition resulting in a discontinuity of muscular coordination is another hypothesis.[62] Lee et al.[63] examined the histology of ureteric smooth muscle and collagen in obstruction employing computer-assisted color image analysis. They have found that the tissue matrix collagen ratios (collagen: smooth muscle) were significantly higher in patients with megaureters compared to the control.
4. Disturbance in the electric syncytium along with the nexus injury has been suggested to precede pathological innervation.[64] Dixon et al.[65] showed dense nonadrenergic innervation in a smooth muscle collar surrounding the terminal ureter in cases of an obstructed megaureter associated with ectopic ureteric insertion. Recently, it was reported that the myocyte apoptosis and decrease in the interstitial Cajal cells in the longitudinal muscular layer of the intravesical part of the ureter may lead to the development of the aperistaltic segment and subsequently to the UVJ obstruction.[66,67]

Prenatal diagnosis

Usually ureter is not seen in fetal scans. Visualization of the dilated ureter to the level of the vesicoureteric junction without abnormal bladder may suggest obstruction or reflux. However, this may be a transient phenomenon. Fetal urine flow is four to six times greater before birth than after and is due to differences in renal vascular resistance, glomerular filtration, and concentrating ability. This high outflow contributes to ureteral dilatation. Another contributing factor is increased compliance of the fetal ureter.[68]

Clinical features

The widespread use of maternal ultrasound has changed the age of presentation of congenital uropathies, including the megaureter. Currently, about half of the cases are asymptomatic and discovered on prenatal ultrasound. The commonest mode of clinical presentation is UTI.[69,70] Microscopic hematuria is frequent and may occur in the absence of infection. This is presumably caused by the disruption of mucosal vessels of the ureter secondary to ureteric distension. The primary obstructive megaureter is more common in males than females, and the left ureter is more likely to be involved than the right. Between 17% and 34% of the patients have bilateral megaureters. Contralateral renal agenesis is found in 10% of the patients.[71–76]

Diagnosis

Antenatally diagnosed ureteral dilatation needs further evaluation to confirm or exclude obstruction, reflux, or both. Clinicians are confronted with the two basic problems in assessing the dilated ureter in a neonate.[6,71,72,75–77] First, it is a real challenge to differentiate between obstructive and nonobstructive urinary tract dilatations. Second, there is no study that can determine accurately the potential of the kidney to recover after relief of obstruction.

Ultrasound

In antenatally detected cases, ultrasonography should be performed between 3 and 5 days after birth. If no dilatation is seen, repeat ultrasound should be performed after a few weeks as neonatal oliguria can mask dilatation. If dilatation persists on a repeat ultrasound, further workup can be postponed for a few weeks unless bilateral disease or a serious abnormality such as obstruction in a solitary kidney or urethral valves is suspected. Such an approach allows for the expected changes of transitional renal function in the newborn period that might otherwise cause inaccuracies with many diagnostic studies. Ultrasonography classically shows hydroureter and variable hydronephrosis, with hyperperistalsis of a lower ureter that terminates shortly above the bladder in a narrow, adynamic segment (Figure 102.5a).[77] However, the narrow segment may not always be visualized, and therefore, micturating cystourethrogram is necessary to exclude VUR.

Renal scintigraphy

Radionuclide scan is required to assess the urinary flow and stasis along with determining the differential function and the glomerular filtration rate. For the evaluation of neonatal hydronephrosis and hydroureter, MAG3 is the most frequently used (Figure 102.5b).

Intravenous urography

Intravenous urography may be necessary in equivocal cases to establish the diagnosis. It delineates the anatomy showing a dilated, obstructed ureter (Figure 102.5c). However, it is better to wait for a few weeks for renal maturation to allow concentration of contrast reliability. Occasionally, Whitaker test and antegrade pyelography may be required to establish the diagnosis.

Fung et al.[78] explored ureteral opening pressure as a novel parameter for evaluating pediatric ureterohydronephrosis. Renal pelvic pressure is assessed while simultaneously documenting the passage of contrast material from the distal ureter into the bladder. A pressure increase of 14 cm H_2O within the renal pelvis is consistent with distal ureter obstruction.

As in the diagnosis of PUJ obstruction, MRU has gained a wide popularity in the diagnosis of UVJ obstruction (Figure 102.5d).

Management

It is being increasingly recognized that many antenatal and neonatal ureteral dilatations improve with time.[5,61,70,72] Surgery is indicated in patients with progressive ureteral dilatation and deterioration in renal function. We have published our experience of over 18 years in 79 children (64 boys and 15 girls) with antenatal diagnosis of hydronephrosis, which led to postnatal diagnosis of megaureters, and tried to determine criteria for those who are at risk for surgery.[76] According to the SFU classification of hydronephrosis, 8 RU were with grade 1, 57 with grade 2, 29 with grade 3, and 11 with grade 4 of postnatal hydronephrosis. The mean ureteral diameter was 1.2 cm. RRF was more than 40% in 82 RU, between 30% and 40% in 18 RU, and less than 30% in 5 RU. Only a combination of renal function deterioration of the hydronephrotic kidney of more than 5% and worsening of hydronephrosis (considered as upgrade of SFU) served as the main indication for surgery. Twenty-five (31%) children required surgical correction. The mean age at surgery was 14.3 months (range of 3–60 months). Univariate analysis revealed that SFU grade 3–4 of postnatal hydronephrosis, RRF less than 30%, and a ureteral diameter of more than 1.33 cm were significant independent risk factors leading to reimplantation.

Operation

There are various techniques of reimplanting the ureter in a nonrefluxing manner after excision of an adynamic, narrow segment. The initial approach to the ureter can be either intravesical, extravesical, or combined.[79] The most commonly used techniques for the intravesical approach are Cohen's transtrigonal reimplantation and Politano–Leadbetter operation.

INTRAVESICAL APPROACH

Position

The patient is anesthetized and placed in supine position (Figure 102.6a).

Incision

A low transverse suprapubic skin crease incision is made (Figure 102.6a).

Exposure

The skin flaps are raised by diathermy dissection (Figure 102.6b). The rectus sheath is cut, and two recti are separated in the midline. Peritoneum is pushed upward. The bladder is opened vertically between two stay sutures. A Denis–Brown retractor is placed over the gauze inside the bladder to improve exposure. The ureter openings are inspected. A 3 or 5 Fr infant feeding tube is passed into the ureter, and a stay suture is placed around the tube. This facilitates the handling of the ureter during dissection. An incision is made circumferentially along the ureter opening, and the distal ureter is dissected from mucosa and trigonal muscle. The ureter is freed keeping away from adventitia and mesentery to avoid damage to blood supply (Figure 102.6c).

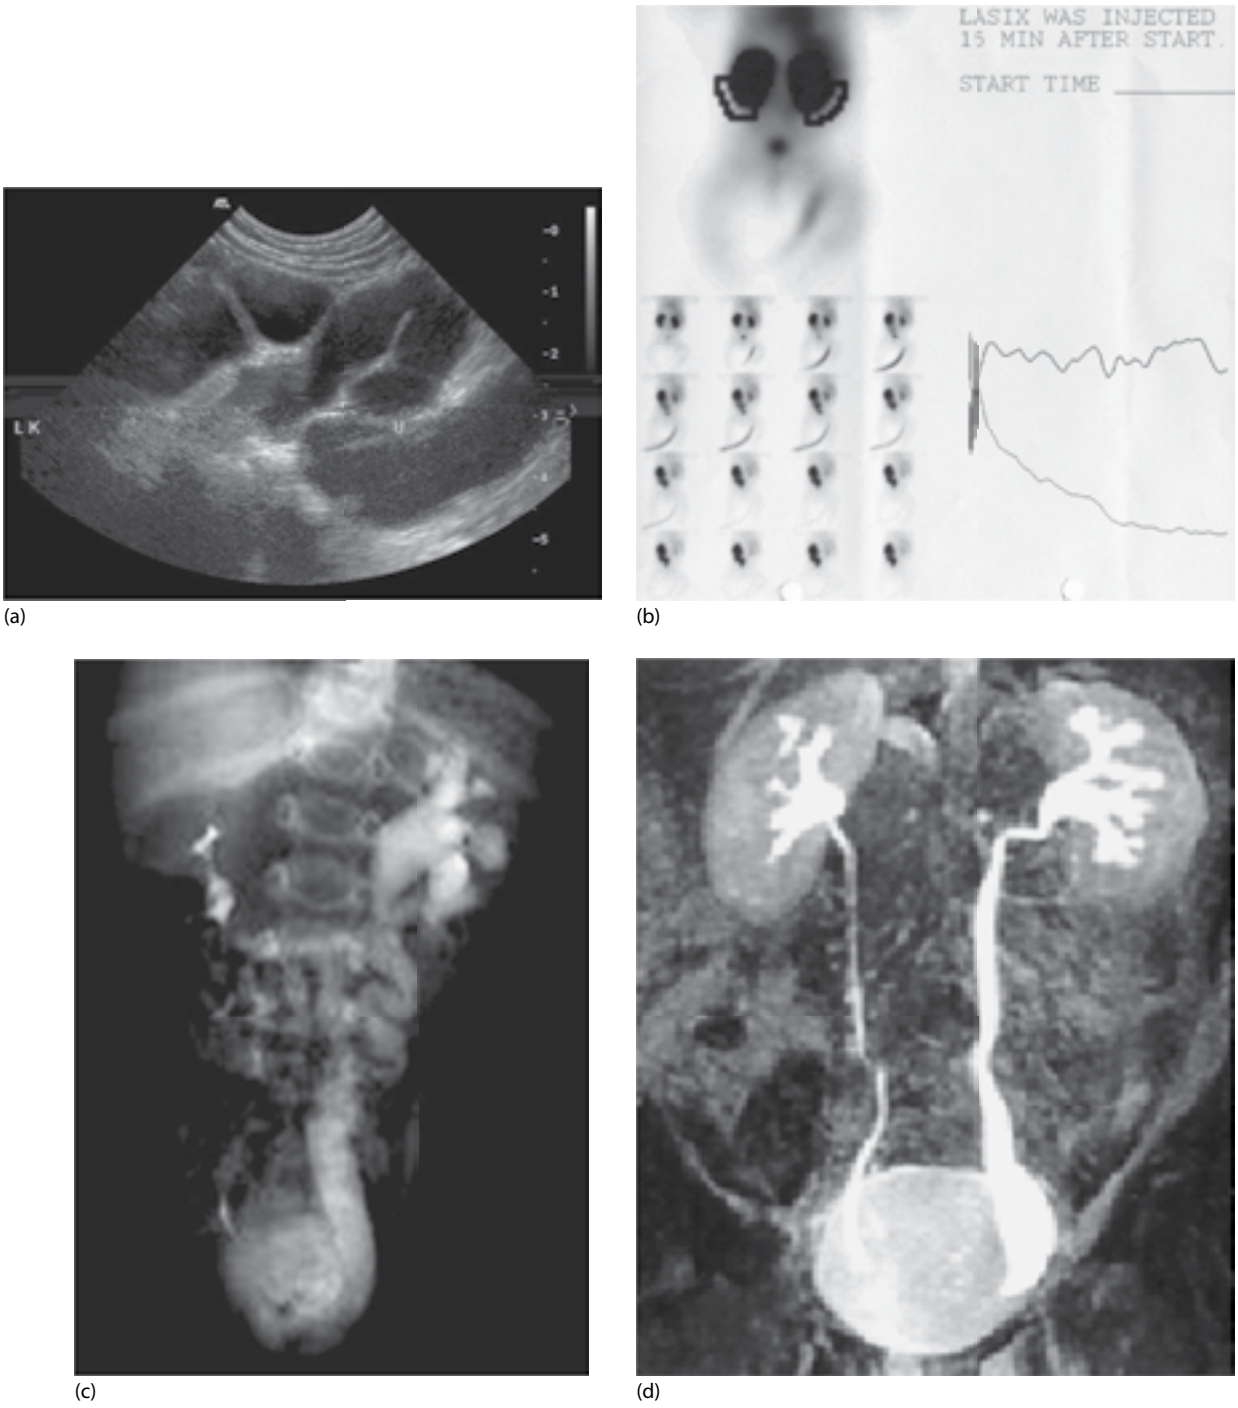

Figure 102.5 **(a)** Longitudinal scan to the left of the midline through the bladder demonstrates dilatation of the left lower ureter to the level of the vesicoureteric junction. **(b)** MAG 3 renal scan. Clearance curve for left kidney demonstrating obstructive pattern. **(c)** 30-minute full-length film from intravenous urogram series shows obstructed megaureter of the same patient. **(d)** MRU image showing obstructive left megaureter.

Bladder opening is narrowed with interrupted absorbable sutures.

COHEN'S METHOD

This method is simple and easier to perform, and is an especially useful technique in infants in whom the bladder is small. An incision is made in the mucosa above and a little lateral to the opposite ureteric orifice. A submucous tunnel is made by inserting the closed blades of scissors and performing an opening and cutting movement. The ureter is threaded through the tunnel (Figure 102.6d). The tunnel should be adequately wide for the ureter and two to three times the ureteric diameter in length to prevent reflux. The terminal narrow portion of the ureter is excised and sent for histology.

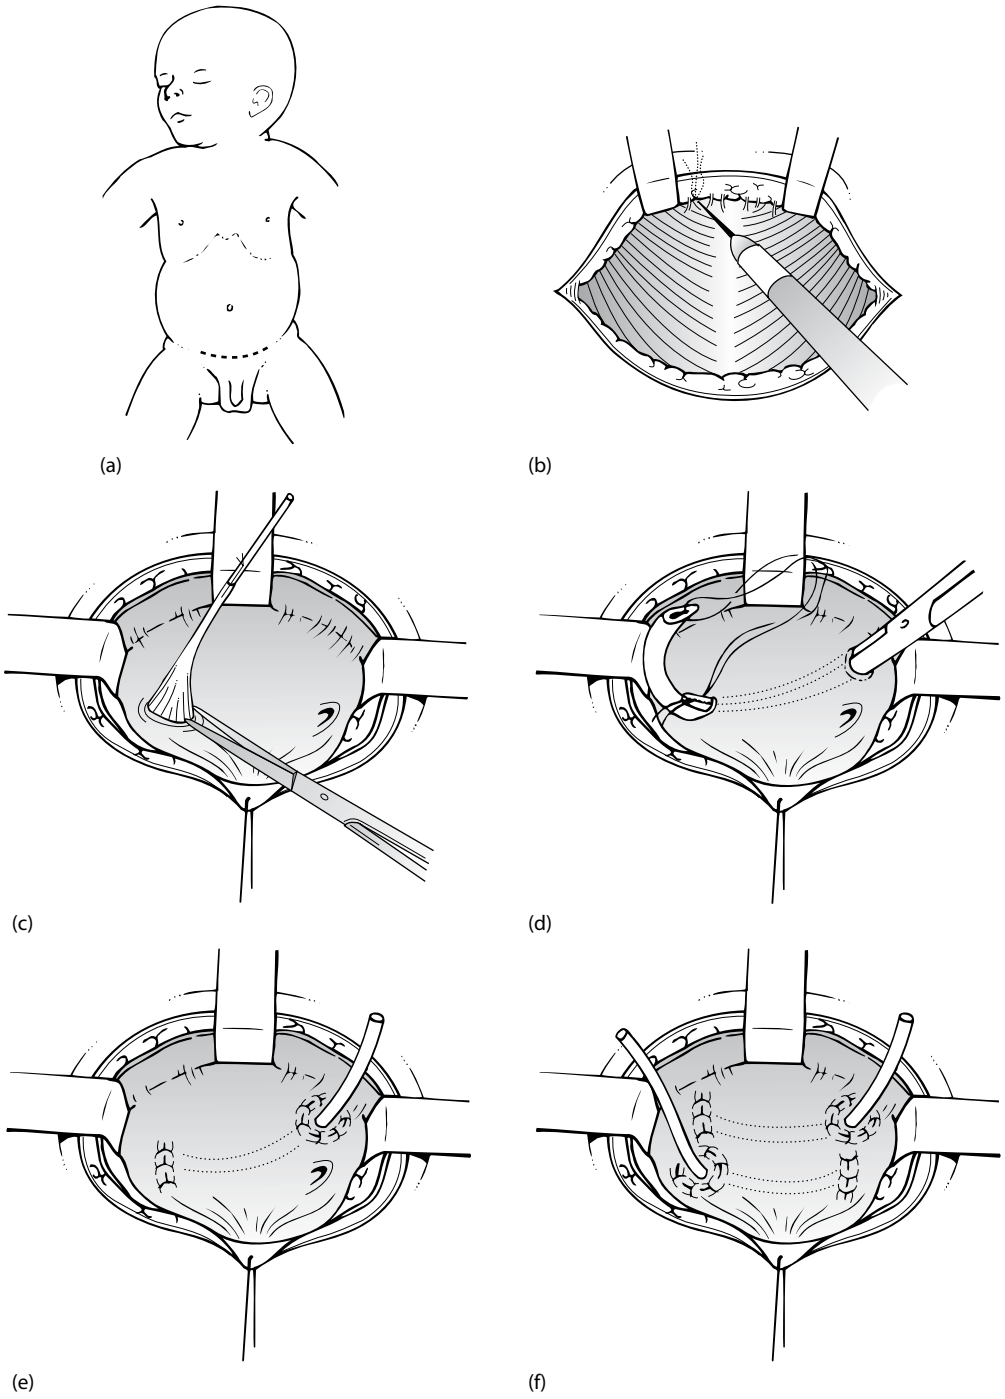

Figure 102.6 Reimplantation of ureter. **(a)** Position of patient on the operating table and line of incision. **(b)** Skin flaps being raised. **(c)** Opened bladder is retracted by Denis–Browne retractor and the stented ureter is dissected free. **(d)** Tunnel is commenced just above and lateral to the opposite ureteric orifice and continued to the original orifice. The ureter is threaded through the tunnel. **(e)** Cuff of the ureter is sutured in position. The original orifice in the bladder is closed. **(f)** In bilateral reimplantation, the second separate tunnel is parallel to the first and ends in the opposite orifice.

If the ureter is very dilated, remodeling is necessary, which may be performed by one of the following methods.

1. A nonexcisional tapering technique has the advantage of avoiding a suture line with potential urinary leakage. However, it is inappropriate for a very dilated ureter as it reduces the diameter by only 50%, and in neonates, it can become too bulky for the tunnel.
   a. Folding (Kalikinski) where a 10–12 Fr catheter is placed into the ureter and a running mattress suture placed proximally and continued distally. The lateral excluded segment is folded posteriorly and its

edge fixed to the medial wall with another running suture.

b. Plication (Starr) of the ureteral wall is achieved by multiple mattress sutures in the antimesenteric border.

2. Excisional tapering technique where part of the ureteral wall is excised by using knife and scissors or Hendren clamps. The remaining ureteral strip is tubularized over 8 Fr double-J stent or feeding tube utilizing a running absorbable suture. The distal end of the ureter is closed with interrupted absorbed sutures to allow for any shortening that might be necessary. The proximal segment of the tailored ureter should stay outside the bladder after completion of the reimplantation in order to avoid a dilated obstruction of the tailored segment.

   The cuff of the ureter is then sutured in position. First, a 4/0 Dexon suture is inserted laterally through the full thickness of the ureter and also through the full thickness of the bladder muscle so as to prevent the ureter from retracting. Next, the bladder and ureteral mucosa are approximated using interrupted 5/0 Dexon. The stents are placed in the ureter (Figure 102.6e). In bilateral reimplantation, the second ureter has its tunnel below and parallel to the first ending in the orifice of the opposite side (Figure 102.6b).

3. Politano–Leadbetter technique: The ureter is further freed up to the dome of the bladder. The new opening for the entrance of the ureter is made on the posterolateral aspect of the bladder. The new submucosal tunnel formed from there to the old ureteric orifice. Then the stay suture of the ureter passed and gently threaded through the new tunnel. The narrow terminal portion of the ureter is excised, the ureter is narrowed by one of the above techniques if needed, and the neo-ureter opening is fixed at the old opening with 5/0 Dexon. Stents are put in place.

   A suprapubic catheter is left in the bladder and the bladder closed in two layers, the mucosa with 4/0 plain catgut and the muscles with 4/0 Dexon. A retropubic drain is brought out through a separate incision and the muscles are approximated with 3/0 Dexon. The rectus sheath is sutured with 3/0 Dexon and the skin approximated with 5/0 Dexon subcuticular stitch.

Endoscopic repair of ureter

Recent progress in endoscopic tools (such as miniscopes, balloons, and guide wires) has led to the widespread use of endoscopy for ureteral repair.[80,81] Some suggested that a simple insertion of the double-J stent into the obstructive ureter for 6 months may solve the problem.[82] Others have advocated balloon dilatation of the obstructed segment with 3.5 Fr dilating balloon, which is inflated to 12–14 atm, or until disappearance of the stenotic obstructive area.[83] This technique demonstrated 90% success rate not only in the short-term period but also in the long-term follow-up. Barat et al.[85] recently reported preliminary results with endoureterotomy for congenital megaureters. The technique consists of incision of the obstructive segment of the ureter, which is inserted into the ureteral orifice ureteroscope. All of the layers of the ureter are incised in the long axis through the entire obstructive segment to expose the periureteral areolar tissue. A double-J stent is inserted for 3 weeks after the procedure. The risk of secondary reflux, which is a main concern after this type of procedure, has not been systematically checked. The role of endoureterotomy in the treatment of megaureters in children has not been widely established. Recently, some authors have advocated a laser incision on the obstructive segment following balloon dilatation at the same setting.[84] Although the initial results in the small group of patients were promising, long-term follow-up into adolescent period is required.

In some small children with a severe obstructive megaureter, refluxing ureteric reimplantation was suggested as a novel method to temporize an obstruction.[86] The treatment consists of anastomosing the ureter proximal to the obstruction to the dome of the bladder in a freely high-grade refluxing fashion. This technique allows time for the child to mature while accurately establishing renal function and preparing for a definitive surgical solution. We as well as others have employed end cutaneous ureterostomy in small infants, when the surgical treatment of a severe megaureter can pose formidable technical challenges, as an ideal way to release an obstruction and to allow the hydronephrosis to subside and to restore, or at least to preserve renal function while awaiting definitive ureteral reimplantation.[87]

Laparoscopic reimplantation

In recent years, laparoscopic reimplantation has gained popularity in some medical centers.[88–91] Employment of robot-assisted laparoscopic techniques in pediatric urology led to even wider application of laparoscopic reimplantation to the surgical armamentarium. Three procedures have been attempted laparoscopically: extravesical reimplantation, Gil–Vernet procedure, and the Cohen cross-trigonal reimplantation. Some difficulties were noticed with this approach such as long operative time, steep learning curve, and the technical challenges in the creation of a submucosal channel without injury to the intact bladder mucosa, and suturing aspects of the procedure. Utilization of the robot-assisted technique is supposed to overcome these difficulties. A recently published review of the national database of ureteral surgery from the United States showed that robot-assisted ureteric reimplantation still appears to be in its adoption phase and is clustered at a small number of hospitals.[91] The new da Vinci XI robot with 8-mm trocars might further optimize four-quadrant surgeries and probably will facilitate incorporeal dissection and suturing even in small infants.

POSTOPERATIVE COURSE

Patients are fasted for 24 hours in case of development of ileus. Ureteral reimplantation using the extravesical

approach can be performed without stenting.[92,93] An indwelling urethral catheter is placed usually for 3–5 days to avoid urinary retention. If a double-JJ stent is used, they can be removed 7–10 days following surgery.

Complications

Complications include wound infection, vesicoureteral reflux due to short tunnel with no effective flap valve mechanism, or obstruction due to a fibrotic distal end secondary to ischemia.

Follow-up and results

Radiologic studies are used to assess initial and long-term surgical results and to monitor renal growth. These include ultrasound, intravenous urography, or radionuclide scans. The success is measured by normal urinary drainage with no reflux and control of urinary infections.

Ureteral duplication anomalies

PREM PURI AND HIDESHI MIYAKITA

INTRODUCTION

Duplication of the ureter and renal pelvis is the most common upper urinary tract anomaly with a reported incidence of 0.8%[1] in the population and in 1.8%–4.2% of pyelograms.[2–5] The vast majority of these anomalies have normally developed renal moieties and cause nonfunctional problems. However, they can challenge the diagnostic acumen with a wide variety of manifestations. Complete duplex systems may be associated with vesicoureteral reflux (VUR) or may be ectopic or subtended by an ectopic ureterocele. Incomplete duplex systems are most often associated with ureteroureteral reflux or ureteropelvic junction obstruction of the lower pole of the kidney.[6,7]

EMBRYOLOGY

The ureteric bud appears at 5 weeks' gestation from the place where the Wolffian duct bends centrally and medially to the cloaca and pushes into the pelvic metanephrogenic mass and eventually forms the ureter and renal pelvis. Premature division of the ureteral bud gives rise to incomplete duplication. If two ureteral buds arise from the Wolffian duct and if both are incorporated into the urogenital sinus, then complete duplication occurs. The upper pole ureter is more closely associated with the Wolffian duct, while the lower pole ureteric bud is closest to the urogenital sinus and incorporated first. The upper pole ureter is carried medially and caudally along with the Wolffian duct. Therefore, the upper pole ureter opens more medially and inferiorly than the lower pole ureter, according to the Weigert–Mayer law.[8–10] Sometimes this upper pole ureter has an abnormally prolonged or close attachment to the Wolffian duct, which will migrate into the segment of urogenital sinus that is destined to become the urethra.

Occasionally in males, a separate opening into the urogenital sinus is not established and the bud continues to be linked to the Wolffian duct much longer, and the ureter comes to insert in the male genital tract such as in seminal vesicles, vas deferens, or even epididymis.

Stephens[11] proposed that, in females, the fused Mullerian ducts after penetrating the urogenital sinus undergo significant epithelial activity and incorporate any Wolffian duct remnants; thus, the ureteral bud along with the Wolffian duct may be carried along as part of caudal Mullerian migration, and this in turn would lead to drainage sites into the vestibule, vagina, cervix, and uterus.

CLASSIFICATION

A standard set of definitions used to describe ureteral duplications anomalies now exists. These definitions were established by the Urologic Section of the American Academy of Pediatrics Committee on Terminology, Nomenclature and Classification.[12] The following are the different types of ureteropelvic duplications, the recognition of which is important in understanding the pathophysiology, clinical manifestations, and management:

1. Incomplete ureteral duplication, where two ureters unite and enter the bladder through a common orifice.
2. Complete ureteral duplication
   a. Intravesical: Two ureters drain separately into the bladder. The upper pole opens caudal and medial to lower pole ureter and has a longer ureterovesical course and therefore less risk of reflux.
   b. Extravesical: Where the ureter opens into the urethra or genital tract.
3. Inverted Y ureteral duplication. Two distal ureters fuse to drain a single kidney; one of the limbs may be ectopic, blind-ending, or atretic.
4. Blind bifid ureter. One branch ends blindly, and this is thought to be because one ureteral bud does not join the metanephrogenic mass.
5. Ureteral triplication and even quadruplication have been reported and are due to formation and/or division into three or four buds.[13–15]

CLINICAL MANIFESTATION

Most often, ureteral duplication anomalies are discovered incidentally unassociated with any symptoms. Infants may come to medical attention because of the complications of obstruction of the upper moiety or infection. VUR is common, occurring much more frequently in the lower segment and is present in 70% of children with duplex systems who present with urinary tract infections.[1,16]

A total of 60% of duplex systems have bifid ureters, with 40% showing complete ureteral duplication. Duplication affects both sides equally, while 15% of patients have bilateral duplications. It is more common in females, who are more likely to exhibit pathological complications. The 8%–11% prevalence of duplex anomalies in females was reported,[17,18] and girls were affected about two times more often than boys.[6]

There is a familial tendency with the risk of duplication in a sibling up to one in eight and is suggestive of autosomal dominant inheritance with incomplete penetration.[4,19] A recent study reported prevalence of duplex systems in familial VUR.[20] Duplex systems were present in 39 (7.6%) of the 513 siblings with VUR. Families with exclusively boys affected with VUR had significantly higher rate (15%) of duplex systems than in families with mixed affected siblings and girls.

Ureterocele, a cystic dilatation of the terminal intramural segment of the distal ureter, is classified as either simple or ectopic.[12] The ectopic variety is symptomatic in infants far more commonly than simple ureterocele and is nearly always with an obstructed upper segment of a duplex kidney. The bulging ureterocele protrudes into the intravesical space and terminates ectopically at the bladder neck or in the urethra. Whether associated with single or duplex systems, the problems of ureterocele are much more common in girls than in boys.

Ureteral duplication can present with diverse clinical manifestations and include the following:

- Urinary tract infection, which may be due to reflux or obstruction. This can vary from overwhelming sepsis to asymptomatic bacteria.
- Epididymo-orchitis as a result of an ectopic ureter opening into the male genital tract.
- Incontinence, which is due to an ectopic ureter opening beyond the sphincter and is thus more common in females or because of infection causing urge incontinence.
- Urinary retention. A ureterocele occupying the bladder neck can cause urinary retention and overflow incontinence. Rarely, it may prolapse through the urethra (Figure 103.1).
- Abdominal mass. Hydronephrosis secondary to obstruction may present with abdominal mass.
- Failure to thrive, because of chronic persistent urinary infection.

Figure 103.1 Ureterocele prolapsing through the urethra in a newborn.

Prenatal diagnosis

The kidneys can be imaged at the 12th gestational week by abdominal ultrasound. With the increased availability and use of maternal ultrasonography, the incidence of urinary tract disorders diagnosed in utero has increased considerably. Oligohydramnios or anhydramnios in the mother is usually due to diminished amniotic fluid. Because amniotic fluid after 18 weeks of gestation is voided urine, it suggests bilateral renal agenesis or outflow obstruction. In order to be certain that renal development is normal, ultrasound at or beyond 20 weeks of gestation is necessary. An obstruction anomaly is recognized by demonstrating a dilated renal pelvis, calyces, or ureter. However, it is not possible to detect an uncomplicated duplex anomaly prenatally.[21] Detection of duplex kidney in the prenatal period offers several potential benefits. For affected fetus, there is the opportunity to plan postnatal management to minimize the risk of long-term renal impairment, by early administration of antibiotics, investigation, and treatment.

Postnatal diagnosis

Ultrasonography, which does not visualize the excretory pathway, may be unable to differentiate between kidneys with and without pyeloureteral duplication, but is able to recognize thick transverse intermediate cortical mass (1 cm) in the latter group and also on the basis of the ratio between the longitudinal and transverse diameter, which is greater than in kidneys without duplication.[22] An obstructed or refluxing system and ureteroceles can be visualized on the ultrasound scans (Figure 103.2).

Micturating cystourethrograms will delineate reflux and ureteroceles. Despite its declining role in the routine evaluation of infants with UTIs, intravenous urography is a useful and easily available modality of investigation.[23] It accurately defines the anatomy, while in the nonfunctioning segment the remaining pole will exhibit the "drooping lily" sign (Figure 103.3). Radionuclide scans are useful in determining the differential function.[24] Computerized tomography and magnetic

Figure 103.2 Sonographic appearance of a ureterocele within the bladder.

Figure 103.3 Twenty-minute film from urogram showing "drooping lily" sign on the left as a consequence of an obstructed nonfunctioning upper moiety on this side due to a large ureterocele.

resonance imaging (MRI) scans may help to define the anatomy of kidneys, and MRI is particularly useful in cases where conventional imaging fails to delineate occult dysplastic renal moieties, ectopic ureters, and ureteroceles. Diagnosis is usually confirmed by cystoscopy and endoscopic visualization of the ureteral orifices. It also helps to assess the extent of ureterocele.

MANAGEMENT

Asymptomatic uncomplicated ureteral duplications do not require active clinical management.

Vesicoureteral reflux

VUR is the most common problem associated with ureteral duplication and is more common in lower poles than in upper poles. Most of the recent reports suggest that there is no difference in the rate of spontaneous resolution of minor grades of reflux into single ureters or lower pole ureters in duplex systems.[24–27] Medical surveillance should be continued in these patients to prevent renal scarring. High-grade VUR in duplex systems is unlikely to resolve and generally considered an indication for surgical treatment.[16,25] Comparing the outcome of VUR in duplex systems with VUR in a single system, it was found that VUR in duplex systems was resolved in only 7% of refluxing units with grade III and none of those with grades IV and V at a median follow-up of 33 months.[16] The reported rates of spontaneous resolution of grades I and II reflux in duplex systems vary from 22% to 85%.[25–27]

In the newborn period, conservative antimicrobial treatment combined with full urological investigations is the management of choice. Infants with grades I–III reflux should continue on chemoprophylaxis. High grades of reflux in infants associated with ureteral duplication, breakthrough infections in spite of prophylaxis, and progressive renal scarring and poor function constitute indications for antireflux operation[28,29] or endoscopic correction.[30]

Polar nephroureterectomy is performed in patients who have one pole ureter reflux with poorly functioning segment of kidney, while nephroureterectomy may be necessary if both poles are involved. Recently, the role of laparoscopic heminephrectomy in pediatric patients has begun to be appreciated.[31–34] Both transperitoneal and retroperitoneal laparoscopic techniques have been used for heminephrectomy in infants and children. The transperitoneal approach for moiety excision is technically simple and offers the added advantage of complete ureterectomy. The retroperitoneal approach, although technically more challenging, offers the advantages of a direct access to the kidney, minimal mobilization of kidney and surrounding structures, and a decreased risk of intraperitoneal organ injury and postoperative adhesions.

In patients with lower pole reflux only in complete ureter duplication, Ahmed and Boucout[29] and Bivens and Palken[35] recommend ipsilateral ureteroureterostomy when there is no abnormality on the contralateral side, or there is history of bladder operation or abnormality thickened bladders. They propose that this operation has fewer complications and requires shorter hospitalization, no postoperative bladder catheters are required, and, as the nonrefluxing ureteral orifice and submucosal tunnel are not disturbed, there is no risk of creating reflux. This can be undertaken either by suprapubic incision or extraperitoneal iliac fossa incision. Ureteroureterostomy would be carried out for complete ureteral duplication associated with VUR, obstructing ureterocele, and ectopic ureters, as well as using laparoscopic surgery.[36,37] The significant discrepancy in ureteral size did not preclude ureteroureterostomy.

Another surgical option is reimplantation of ureters. Only a refluxing ureter may be undertaken if it can be safely

separated. In patients with reflux into both ureters and those where the refluxing ureter cannot be safely separated, common sheath ureteric reimplantation is undertaken. Ellsworth et al.[38] reported 10-year experience with common sheath reimplantation in 54 refluxing units. Common sheath reimplantation yields a 98% success rate with minimal morbidity. Recently, laparoscopic extravesical transperitoneal ureteral reimplantation using the Lich–Gregoir procedure was developed in refluxing duplicated collecting systems.[39] Furthermore, robot-assisted laparoscopic surgery is spreading ureteral reimplantation as well as heminephrectomy.[40,41] All procedures were successfully completed laparoscopically, and reflux was corrected in all children.

In incompletely duplicated ureters, surgical options include reimplantation of the common distal ureter if the junction is proximal or when the junction is close to bladder excision of the common segment, with reimplantation of both ureters in the bladder or ureteroureterostomy with reimplantation of one ureter. However, if the function is poor, nephroureterectomy is necessary to avoid a diverticulum-like defect.

Minimally invasive endoscopic technique for the correction of VUR has become an established alternative to long-term antibiotic prophylaxis and surgical treatment. Endoscopic subureteric Deflux® injection is effective in treating duplex reflux of higher grades in complete and incomplete systems.[28,42,43] The technique of endoscopic injection of Deflux® is simple and straightforward. With an incomplete duplex system, the technique is the same as in a single system. All cystoscopes available for infants and children can be used for this procedure. The disposable Puri flexible catheter (STORZ) or a rigid metallic can be used for injection. A 1 ml syringe filled with Deflux® is attached to the injection catheter. Under direct vision through the cystoscope, the needle is introduced under the bladder mucosa 2–3 mm below the affected ureteral orifice at the 6 o'clock position. In children with grades IV and V reflux with wide ureteral orifices, the needle should be inserted not below but directly in the affected ureteral orifice. The needle is advanced about 4–5 mm under the mucosa and the injection started slowly. As the Deflux® is injected, a bulge appears in the floor of the submucosal ureter. A correctly placed injection creates the appearance of a nipple on the top, which is a slit-like or inverted crescent orifice (Figures 103.4 and 103.5).

In the case of a complete ureteral duplication, the needle is introduced 2–3 mm below the lower ureteric orifice at

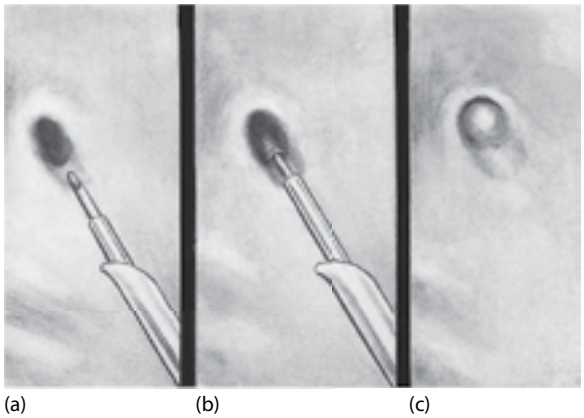

Figure 103.4 Technique of subureteric injection in an incomplete duplex system. **(a)** Site of placement of needle. **(b)** Injection in progress. **(c)** Slit-like orifice at the finish of injection.

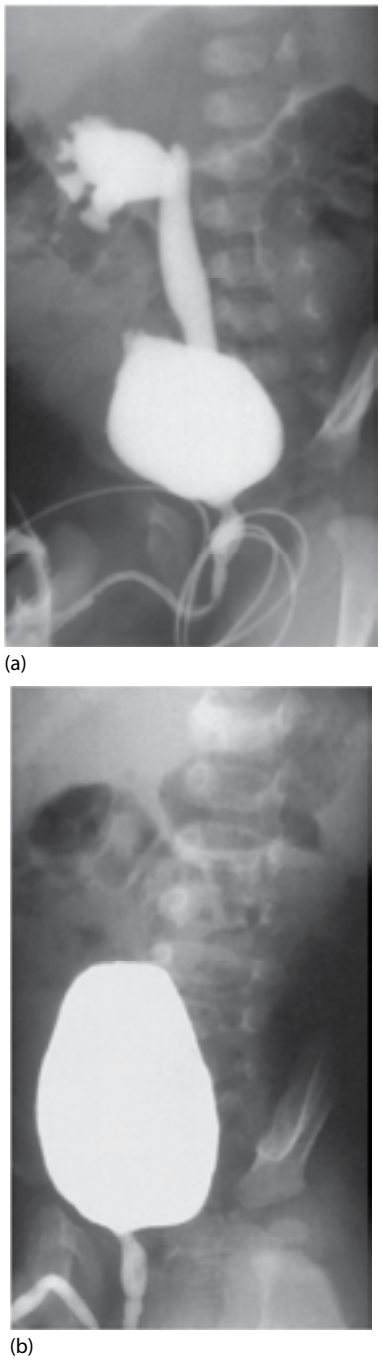

Figure 103.5 **(a)** Micturating cystogram in an 8-week-old boy shows grade IV vesicoureteric reflux into the lower moiety of the right duplex system. **(b)** Micturating cystogram in the same boy following endoscopic correction of reflux.

the 6 o'clock position, but the entire length of the needle (8 mm) is advanced behind the two ureters. During injection, the needle is slowly withdrawn until a "volcanic" bulge of paste is seen and the two ureteric orifices look slit-like (Figure 103.6). Patients are treated as day cases, and a voiding cystourethrogram and ultrasound are performed 6–12 weeks after discharge.

Ureteropelvic junction obstruction

In the bifid system, obstruction commonly involves the lower pole.[34–38] Upper pole ureteropelvic junction obstruction is uncommon (Figure 103.7a and b). In patients with low bifurcations and who have long ureteral segments, a standard pyeloplasty can safely be performed. If the lower pole ureteral segment is short, an end-to-end anastomosis of the lower pole pelvis to the upper pole ureter, eliminating the short lower pole ureter, may be necessary. Alternatively, the short lower pole ureter is retained and incorporated into a wider anastomosis. In patients with incomplete duplications, it is possible to widen the narrowed junction of the lower pole segment to the upper pole ureter by making a vertical incision in the anterior wall and suturing it transversely.[44] If there is nonfunction of the obstructed segment, a heminephroureterectomy to the level of the bifurcation is necessary to avoid leaving a ureteral stump into which ureteroureteral reflux can occur.[44]

The management of ureterocele is complex.[45–47] Consideration of ureterocele as intravesical or extravesical is important because the technique of surgical reconstruction can be different. If the function is good, endoscopic incision of the ureterocele may be tried. The advantage of this procedure is that this is straightforward management, especially in septic babies. The obstruction can be solved by simple puncture of ureterocele rather than endoscopic incision. The reflux rate to the ureterocele moiety following endoscopic puncture is negligible. We have used in all our babies a stylet of the 3-Fr ureteral catheter for endoscopic puncture. The puncture hole is made high enough and lateral on

the ureterocele in order to avoid reobstruction and to create postpuncture flap sufficient to preserve the flap-valve antireflux mechanism. If the reflux developed after endoscopic puncture, it is usually a low grade and does not require any treatment. If the child develops breakthrough infections or high-grade reflux, endoscopic correction of reflux can be easily performed.[30]

Vesicoureteral reflux

PREM PURI AND MANUELA HUNZIKER

INTRODUCTION

Primary vesicoureteral reflux (VUR)—the retrograde flow of urine from the bladder into the upper urinary tract—is the most common urological anomaly in children. It occurs in 1%–2% of the pediatric population and in 30%–50% of children who present with urinary tract infection (UTI).[1,2] The association of VUR, UTI, and renal damage is well known. Marra et al.[3] reviewed data on children with chronic renal failure who had high-grade VUR in the Italkid project, a database of Italian children with chronic renal failure, and found that those with VUR accounted for 26% of all children with chronic renal failure. Parenchymal injury in VUR occurs early, in most patients before age 3 years. Kidneys of young infants are more vulnerable to renal damage. Most renal scars are present when reflux is discovered at initial evaluation for UTI. One of the main goals of treating the child with VUR is prevention of recurring febrile UTIs and minimizing risk of renal damage and long-term renal impairment.

The hereditary and familial nature of VUR is now well recognized, and several studies have shown that siblings of children with VUR have a much higher incidence of reflux than the general pediatric population. Prevalence rates of 27%–51% in siblings of children with VUR and a 66% rate of VUR in offspring of parents with previously diagnosed reflux have been reported.[4–8] However, because VUR can resolve spontaneously with age, it is difficult to accurately determine the exact prevalence in family members. It has become evident that familial clustering of VUR must have a genetic basis, but no single major locus or gene for VUR has yet been identified, and most researchers now acknowledge that VUR is genetically heterogeneous.[9]

ETIOLOGY

Urinary tract development in the embryo begins with the formation of the ureteric bud, which is an outgrowth of the mesonephric duct. Growth of the ureteric bud is stimulated by reciprocal signaling between the bud and the metanephrogenic mesenchyme, and results in the formation of the ureter and branching to form the collecting ducts. Signaling between the bud and the mesenchyme stimulates the metanephrogenic mesenchyme to form the kidney. Apoptosis occurs in the part of the mesonephric duct between the newly developed ureter and the urogenital sinus. The free end of the developing ureter inserts into the bladder wall and forms the vesicoureteric valve.[9]

The ureterovesical junction (UVJ) acts as a valve and closes during micturation or when the bladder contracts. The UVJ is structurally and functionally adapted to allow the intermittent passage of urine and prevent the reflux of urine into the bladder. The main defect in patients with VUR is believed to involve the malformation of the UVJ, in part due to shortening of the submucosal ureteric segment due to congenital lateral ectopia of the ureteric orifice. This leads to retrograde flow of urine into the ureter or kidney. Since VUR primarily involves abnormalities of the ureter and ureteric orifice, it has been suggested that the timing and positioning of branching of the ureteric bud from the Wolffian duct may be related to VUR. Many genes are involved in the ureteric budding and subsequent urinary tract and kidney development. Primary VUR could be due to mutations in one or more developmental genes that control these processes.

Mechanism of renal scarring

The association between VUR and renal scarring is now widely recognized. Scarring is directly related to the severity of reflux. Belman and Skoog[10] assessed renal scarring in 804 refluxing units and found renal scars in 5% of those with grade I reflux, 6% of those with grade II reflux, 17% of those with grade III reflux, 25% of those with grade IV reflux, and 50% of those with grade V reflux.

The mechanism by which reflux produces renal scars is still not clear. Renal parenchymal damage can be congenital or acquired. Congenital reflux nephropathy occurs as a

result of abnormal embryological development with subsequent renal dysplasia and is largely seen in male infants with high-grade VUR. Exposure to UTIs in patients with congenital renal dysplasia can lead to progression of renal parenchymal damage. Both experimental and clinical studies have shown that acquired renal scarring associated with VUR is the result of an acute inflammatory reaction caused by bacterial infection of the renal parenchyma.[11] It is well known that the risk of renal scarring after an episode of pyelonephritis is increased in children with high-grade VUR, affecting up to 89% of children with grades IV–V VUR[12] Exposure to UTIs in patients with congenital renal dysplasia can lead to progression of renal parenchymal damage. Reflux-associated nephropathy is an important cause of hypertension and end-stage renal disease.[13]

Dimercaptosuccinic acid (DMSA) scans have allowed us to follow sequentially the evolution of a scar from an area of decreased blood flow during the acute inflammatory phase to a parenchymal defect indicative of a mature scar. Yet only half of patients with acute pyelonephritis will have such a scar. What converts an acute inflammatory process into a scar in some patients and not in others is not clearly understood. Factors implicated in the formation of a mature scar include the magnitude of the pressure driving the organisms into the tissues, the intrinsic virulence of the organism itself, and the host defense mechanisms. Furthermore, some of the worst examples of renal injury associated with VUR are those that are present at birth. As renal damage at that time cannot be the consequence of infection, such injury is assumed to be developmental in origin, but the pathophysiology of this is not entirely clear.

The three mechanisms considered potential etiologies for renal scar formation are (1) reflux of infected urine with interstitial inflammation and damage; (2) sterile, usually high-grade reflux, which may damage the kidney through a mechanical or immunological mechanism; and (3) abnormal embryological development with subsequent renal dysplasia. Patients in the latter group may also have UTI in the postnatal period, resulting in extensive parenchymal damage. It is well recognized that in the first two groups of renal parenchymal damage, it is essential to discover reflux early before damage can be initiated. In the third group, it is clear that congenital damage currently cannot be prevented. However, in these patients, it is mandatory to discover reflux at the early stages to prevent exposure to UTI and avoid the possible progression of renal parenchymal damage.

DIAGNOSIS

Antenatally diagnosed reflux

Prenatal ultrasonography has resulted in a dramatic increase in the number of infants detected with significant asymptomatic uropathology, allowing treatment before the potential devastating consequences of UTI occur. An incidental anomaly is detected by antenatal ultrasonography in about 1% of studies and 20%–30% involving the urinary tract.[14] By far, the most common abnormal finding is hydronephrosis, comprising over 90% of the urological abnormalities detected. Underlying diagnoses include pelvic–ureteric junction obstruction, vesicoureteric junction obstruction, posterior urethral valves, and VUR.

Although antenatal hydronephrosis is generally considered to represent an obstructive lesion, VUR is not an uncommon cause. In children diagnosed with antenatal hydronephrosis, VUR has been reported in 10%–20%.[15] Skoog et al.[16] published guidelines for screening siblings of children with VUR and neonates/infants with prenatal hydronephrosis. They reported a prevalence of VUR of 16.2% in screened populations with prenatal hydronephrosis. Based on review of data and panel consensus, voiding cystourethrogram (VCUG) is recommended for infants with high-grade hydronephrosis, hydroureter, or abnormal bladder on ultrasound, or who develop a UTI on observation.

Natural history of prenatally diagnosed VUR

The vast majority of infants found to have VUR following detection of antenatal hydronephrosis are males. The male preponderance is reported to range from 2:1 to 5:1 in various series.[17,18] This is in total contrast to the female preponderance that has been consistently reported in later childhood. It is also important to recognize that the calculated ratio between the genders is dependent upon the method of ascertainment. UTIs are more common in females, and it is no surprise that when VUR is detected by screening children who presented with symptoms of UTI, more girls than boys are diagnosed with VUR. However, 80% of cases detected by the appearance of antenatal hydronephrosis on prenatal ultrasound are boys, and these patients often have high-grade VUR-associated renal damage.[19] In approximately two-thirds of the cases, the reflux is bilateral. VUR diagnosed prenatally tends to be of high grade.[17,18]

It also has been reported that boys are more vulnerable to UTI, especially in the first 6 months of life, where different factors play a significant role.[20] Host factors such as the inner nonkeratinized epithelium of the foreskin create a moist reservoir for uropathogens and contribute to the first contact between the host and the bacteria. Once the prepuce has been colonized, the bacteria can ascend the urinary tract, causing cystitis or pyelonephritis. Rushton and Majd[20] showed a clear predominance of males among infants less than 6 months old with febrile UTI, and a disproportionately high frequency of uncircumcised male infants. Cascio et al.[21] showed a pure growth of a uropathogen in 48% of uncircumcised infants with VUR despite the use of prophylactic antibiotics.

A meta-analysis performed by Skoog et al.[16] showed that VUR in infants diagnosed by screening after an antenatally detected hydronephrosis was significantly associated with renal damage. Renal abnormalities occurred in a mean of 6.2% versus 47.9% of those with grades I–III versus IV–V reflux.[16]

Yeung et al.[19] studied 155 infants with prenatal hydronephrosis and postnatally diagnosed VUR. They observed renal parenchymal damage in 42% of the 135 infants (101 male and 34 female) without history of UTI. Furthermore, Nguyen et al.[22] reported renal parenchymal abnormalities in 65% of predominantly male infants with sterile high-grade reflux. The resolution rate of antenatally diagnosed high-grade VUR (grade IV or V) is approximately 20% by the age of 2 years.[14] However, in approximately 25% of boys followed nonoperatively, UTIs developed by the age of 2 years, despite antimicrobial chemoprophylaxis.[14]

Early detection of febrile UTI is critical in infants, who are unable to verbally communicate lower urinary tract symptoms. Detection of VUR by screening infants in at-risk population before presentation with febrile UTI is recommendable, but its outcomes remain unknown.[16]

CLINICAL PRESENTATION

It is obviously important to diagnose VUR at the earliest possible age, preferably in infancy. There are a number of clinical presentations, which should raise the suspicion of VUR in an infant. As antenatal ultrasound becomes increasingly routine, many cases will be suspected before birth and should be investigated within the first month of life. Infants with a poor urinary stream as in posterior urethral valves or infants with spina bifida have a high incidence of VUR, while early investigations are indicated in the first-degree relatives of patients with high-grade VUR.

In most cases, VUR is discovered clinically after investigations for UTI. The incidence of VUR in infants with febrile UTI is 30%–50%, with even higher incidence in male infants. Cascio et al.[23] found VUR in 33% of the 57 neonates investigated for first hospitalized UTI. Sixteen had bilateral VUR and three unilateral, with 91% having high-grade VUR.

RADIOLOGICAL INVESTIGATIONS

Ultrasound

Sonography should be performed in any infant with suspicion of VUR. The bladder and lower ureters are assessed by real-time examination at each ureterovesical junction for dilatation, configuration, peristalsis, and continuity with the bladder base. VUR is suspected in the presence of a dilated pelvicaliceal system, upper or lower ureter, unequal renal size, or cortical loss and increased echogenicity (Figure 104.1a–d). Sonography is not sufficiently sensitive or specific for diagnosing VUR.[18,24,25] The intermittent and dynamic nature of VUR probably contributes to the insensitivity of routine renal sonography in the detection of even higher grades of reflux.

Phan et al.[15] reported a 15% prevalence of VUR in infants diagnosed with antenatal hydronephrosis, many of whom had normal postnatal ultrasound or mild postnatal pelviectasis. They concluded that a micturating cystogram is the only reliable test for detecting postnatal VUR.

Micturating cystography

VUR is a dynamic process. Bladder filling and voiding are necessary for its elucidation, which requires catheterization for adequate documentation. Micturating cystogram remains the gold standard for detecting VUR (Figure 104.2). Despite the unpleasant nature of the procedure, it has a low false-negative rate and provides accurate anatomical detail, allowing grading of the VUR (Figure 104.3a–c). It is commonly performed as a first-line investigation, together with ultrasound.

Some investigators employ nuclear cystography for diagnosing VUR. This can be either direct or indirect using technetium-labeled diaminotetra-ethyl-pentaacetic acid (DTPA). In direct nuclear cystography, DTPA is instilled into the bladder by urethral catheter or suprapubic injection, and the ureters and kidneys are observed on camera during bladder filling and voiding. In indirect nuclear cystography, DTPA is injected intravenously. After the bladder is filled, the patient is instructed to void, and the counts taken over the ureters and kidneys are used to assess the presence of VUR. Indirect nuclear cystography requires a cooperative patient and therefore is of no value in infants. The main disadvantage of nuclear cystography is that it does not give anatomical detail and VUR cannot be graded according to international classification.

According to the international classification of reflux, there are five grades of reflux:

- Grade I, ureter only
- Grade II, ureter, pelvis, and calices—no dilatation, normal caliceal fornices
- Grade III, mild dilatation and/or tortuosity of the ureter and mild dilatation of the renal pelvis—minor blunting of the fornices
- Grade IV, moderate, dilatation and/or tortuosity of the ureter and moderate dilatation of the renal pelvis and calices—complete obliteration of the sharp angle of fornices but maintenance of the papillary impressions in the majority of calices
- Grade V, gross dilatation of the renal pelvis and calices (Figure 104.4)

DMSA scan

DMSA is the most sensitive technique for detecting renal scarring. When performed in the course of acute UTI, the DMSA scan is currently the most reliable test for the diagnosis of acute pyelonephritis. Several reports have suggested that a normal[26,27] acute DMSA scan rules out the possibility of high-grade VUR. However, others have reported that acute DMSA scintigraphy has limited overall ability in revealing VUR after first febrile UTI in infants.[25,28] This was

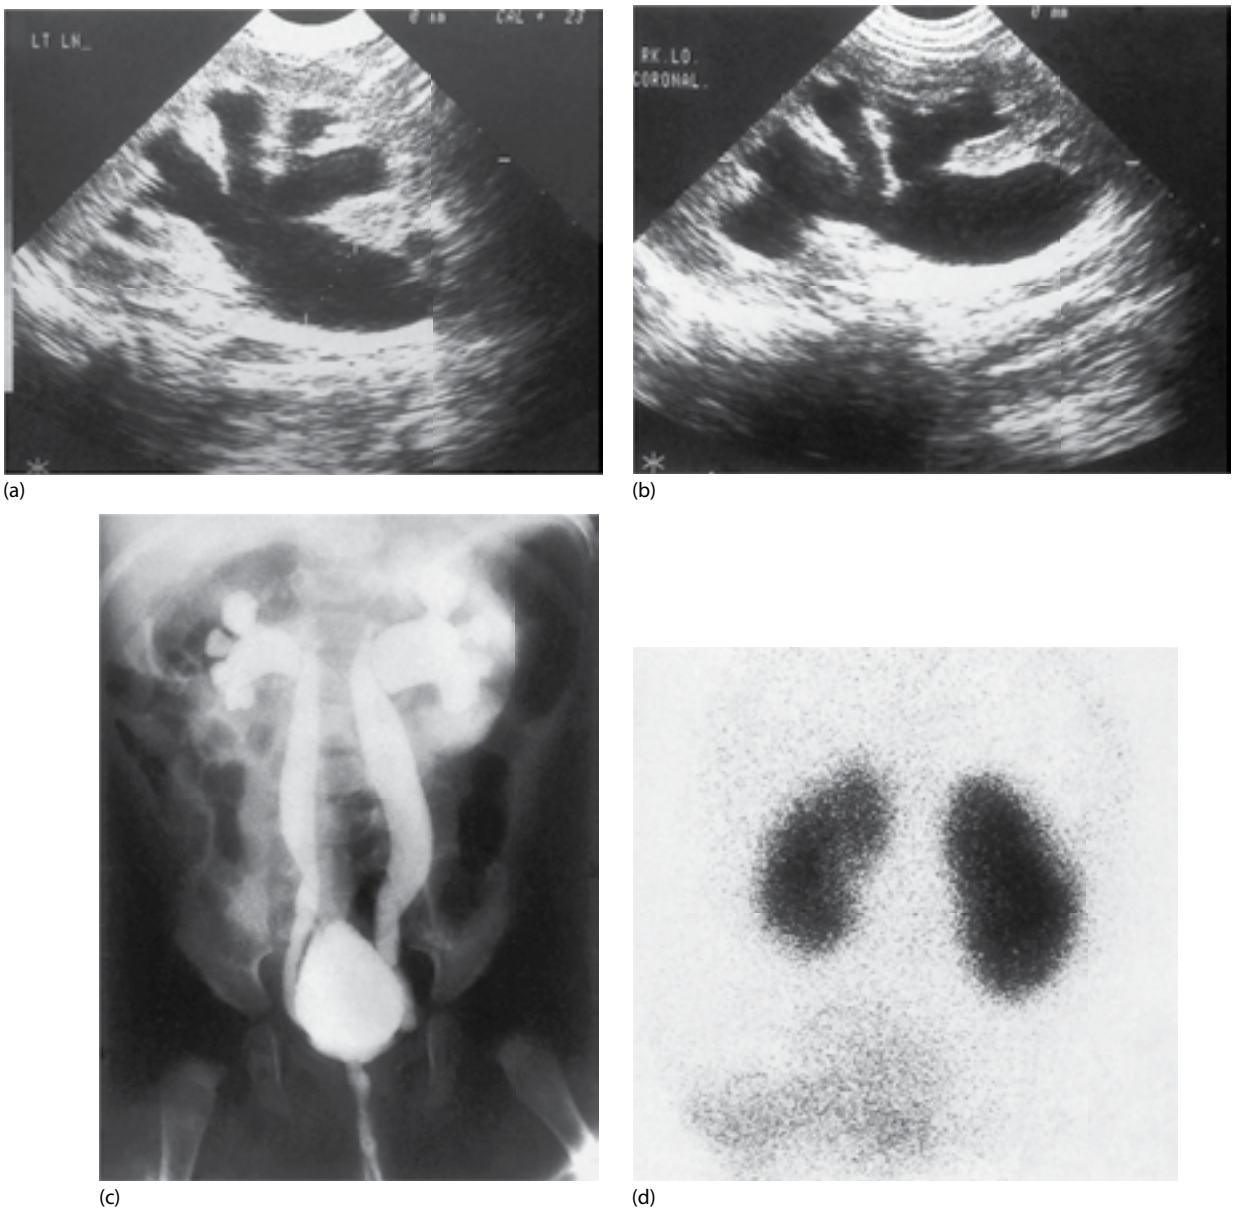

Figure 104.1 **(a, b)** Ultrasound shows bilateral hydronephrosis in a 6-week-old infant. **(c)** Micturating cystography in the same infant shows bilateral high-grade vesicoureteric reflux. Note intrarenal reflux on the left side. **(d)** DMSA scan demonstrates significant left renal scarring, particularly in upper and lower poles.

true even when the findings of the acute DMSA scan were combined with those of renal ultrasonography.

Timing of investigations

Management of VUR has changed over the last few years from only prevention of renal scarring to, in addition, improvement of quality of life and reduction of number of infections and unnecessary diagnostic tests.[29] New international guidelines are reflecting these changes in our understanding of VUR and trying to set up algorithms for clinical management.[29] However, consensus has not been reached today.[30] In the past, micturating cystourethrogram (MCUG) used to be included in all guidelines as an investigation for the assessment of children with UTIs.[31] To date, most guidelines recommend that MCUG is not used routinely and is limited to highly selected cases, although it remains the gold standard to define VUR. The American Academy of Pediatrics (AAP) guidelines do not advocate routine MCUG after the first UTI. MCUG is indicated if renal and bladder ultrasound reveals hydronephrosis, scarring, or other pathological findings.[32] MCUG should be performed in all patients between the ages of 2 and 24 months with recurrent febrile UTI. The National Institute for Health and Clinical Excellence (NICE) guidelines do not recommend the routine use of MCUG in children with recurrent UTI; MCUG is reserved only for exceptional cases. The guidelines from the European Association of Urology (EUA) recommend a more proactive approach with early detection

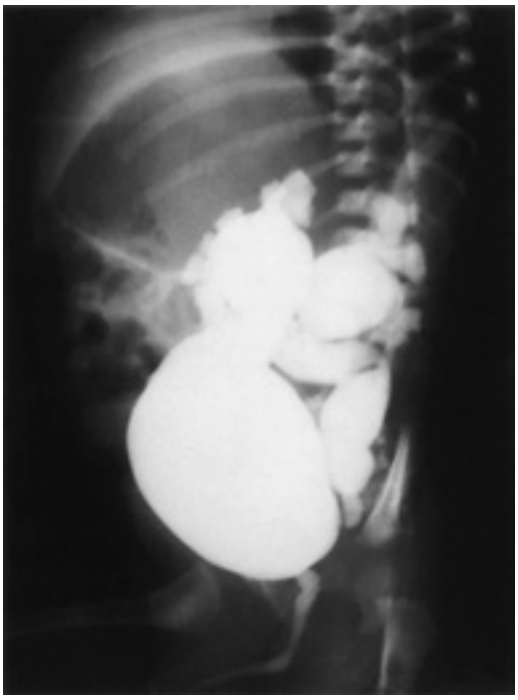

Figure 104.2 Four-week-old male infant with bilateral grade V vesicoureteric reflux. Note normal urethra and bladder wall.

of VUR using MCUG in all children younger than 2 years once a first febrile UTI is confirmed.[33] Nevertheless, most guidelines recommend the routine use of a DMSA scan for the evaluation of patients with recurrent UTIs.[30]

MANAGEMENT

The goals of treating the child with VUR are (1) to prevent recurring febrile UTIs, (2) to prevent renal injury, and (3) to minimize the morbidity of treatment and follow-up.

Management of VUR has been controversial. The various options currently available for the management of VUR are (1) long-term antibiotic prophylaxis, (2) open surgical treatment, (3) observation or intermittent therapy with management of bladder/bowel dysfunction and treatment of UTIs as they occur, and (4) minimally invasive endoscopic treatment.

Medical management

This strategy is based on three important assumptions: (1) Sterile VUR in most cases is not harmful to the kidneys and has no relevant affect on kidney function. (2) Children can outgrow VUR, at least the lower grades. (3) Continuous low-dose antibiotic prophylaxis can prevent infection for many years while VUR is still present.

The patient is required to take low-dose daily antibiotics, and annual ultrasound and VCUG are performed to assess if the reflux has resolved.

Continuing antibiotic prophylaxis is reliant on the patient's compliance and has the risk of bacterial resistance accompanied by potential breakthrough UTIs. Compliance to antibiotic therapy has been reported to be poor. Data of 11,000 children under the age of 11 years with a diagnosis of VUR were reviewed with 76% of VUR patients initiated on antibiotic prophylaxis. Only 17% of pediatric VUR patients on prophylactic antibiotics were compliant with therapy. Of patients on prophylactic therapy, 58% had a diagnosis of a UTI within 1 year of treatment.[34] Furthermore, several large, prospective, randomized controlled trials have shown little or no benefit of medical therapy in terms of reducing the incidence of febrile UTI or renal scarring.[35]

Spontaneous resolution is inversely proportional to the initial grade of reflux.[36] Resolution rates for grade I and II VUR have been reported to be between 80% and 68%, respectively. However, the resolution rate for grade III reflux was only 45% and for grade IV/V VUR only 17%.[37]

The International Reflux Study Group, at 10-year follow-up, showed that 58% of children with grade III and IV reflux randomly allocated to medical treatment still had reflux after 5 years and 27.5% after 10 years.[38]

The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) trial, which is, to date, the largest randomized, placebo-controlled, double-blind, multicenter study, showed that there was a 50% reduction in the risk of recurrent UTI in those children on the prophylaxis. However, antimicrobial prophylaxis did not decrease the risk of renal scarring.[39,40]

Surgical treatment

OPEN ANTIREFLUX PROCEDURES

Open surgical treatment of reflux has been the gold standard. However, surgery is not without risks, and in infants, it is technically more challenging. The majority of the open antireflux procedures entail opening the bladder and performing a variety of procedures on the ureters such as transvesical reimplantation (Politano–Leadbetter technique) and transtrigonal advancement of the ureters (Cohen technique). These procedures, although effective, involve open surgery and prolonged in-hospital stay and are not free of complications, even in the best hands. Although open surgery achieves a success rate of 92%–98% in grades II–IV VUR, the American Urological Association (AUA) report on VUR reported persistence of VUR in 19.3% of ureters after reimplantation of ureters for grade V reflux.[41] The rate of obstruction after ureteral reimplantation needing reoperation reported by the AUA in 33 studies was 0.3%–9.1%.

LAPAROSCOPIC URETERAL REIMPLANTATION

In recent years, several authors have reported their experience of ureteral reimplantation with laparoscopic extravesical transperitoneal approach as well as pneumovesical approach.[42–44] This technique results in a shorter hospital stay and less postoperative discomfort compared to open operation. Furthermore, robotic-assisted laparoscopic extravesical ureteral reimplantation has shown high success rates similar to open ureteral reimplantation as well as minimal morbidity.[45–47]

ENDOSCOPIC TREATMENT OF VUR

The concept of endoscopic treatment was introduced by Puri and O'Donnell[48] in 1984 as a minimally invasive treatment for VUR following a successful experimental study in piglets. Minimally invasive endoscopic technique for the correction of VUR has become an established alternative to long-term antibiotic prophylaxis and open surgical treatment.

The AUA guidelines recently updated the management of primary VUR in children. They extracted data from 131 articles, and data from 17,972 patients were included in their analysis. Success rates are 98.1% for open surgical procedures and 83.0% for endoscopic therapy after one injection.[35] With the high success rate of endoscopic treatment, the AUA guidelines included endoscopic treatment in the management options for VUR.

Endoscopic treatment has several advantages over the two other options. In contrast to long-term antibiotic prophylaxis, it offers immediate cure of reflux with a high success rate, its success does not rely on patient or parent compliance, and the procedure is virtually free of adverse side effects. Long-term administration of antibiotics implies the danger of bacterial resistance with promotion of breakthrough UTIs, and antibiotics are usually needed for years. In 2001, Deflux was approved by the Food and

Drug Administration (FDA) as an acceptable tissue-augmenting substance for subureteral injection therapy for VUR. Since then, endoscopic treatment has become increasingly popular worldwide for managing VUR, and Deflux is the most widely used tissue-augmenting substance.

Recently, the Swedish Reflux Trial in Children recruited children between 1 and 2 years old with grade III–IV VUR for a prospective, open, randomized controlled multicenter study. Children were treated in 3 groups, including low-dose antibiotic prophylaxis, endoscopic therapy, and a surveillance group on antibiotics only for febrile UTI. After 2 years, endoscopic treatment results were significantly better than the spontaneous resolution rate or downgrading in the prophylaxis and surveillance groups.[49]

The technique of endoscopic injection of Deflux is simple and straightforward.[50,51] The patients should be placed in a lithotomy position. The cystoscope is passed, and the bladder wall, trigone, bladder neck, and both ureteric orifices are inspected. All cystoscopes available for infants and children can be used for this procedure. The bladder should be almost empty before proceeding with injection, since this helps to keep the ureteric orifice flat rather than away in a lateral field. The disposable Puri flexible catheter or a rigid metallic can be used for injection. A 1 mL syringe filled with Deflux is attached to the injection catheter. Under direct vision through the cystoscope, the needle is introduced under the bladder mucosa 2–3 mm below the affected ureteral orifice at 6 o'clock position (Figure 104.5). In children with grade IV and V reflux with wide ureteral orifices, the needle should be inserted not below but directly into the affected ureteral orifice. The needle is advanced about 4–5 mm under the mucosa and the injection started slowly. As the Deflux is injected, a budge appears in the floor of the submucosal ureter. Most refluxing ureters require 0.4–1.0 mL Deflux to correct reflux. A correctly placed injection creates the appearance of a nipple on the top, which is a slit-like or inverted crescent orifice. Patients are treated as day cases, and a voiding cystourethrogram and ultrasound are performed 6–12 weeks after discharge.

Between 2001 and 2010, the author treated 1551 infants and children with intermediate and high-grade VUR by endoscopic injection of Deflux. VUR was unilateral in 765 children and bilateral in 786. Renal scarring was detected in 369 (26.7%) of the 1384 patients who had a DMSA scan. Reflux grade in the 2341 ureters was grade II, III, IV, and V in 98 (4.2%), 1340 (57.3%), 818 (34.9%), and 85 (3.6%), respectively. VUR resolved after the first, second, and third endoscopic injection of dextranomer/hyaluronic acid (Dx/HA) in 2039 (87.1%), 264 (11.3%), and 38 (1.6%) ureters, respectively. Of the 1512 patients who were followed up, 69 (4.6%) developed febrile UTIs during a median follow-up of 5.6 years. None of the patients in the series needed reimplantation of ureters or developed any significant complications, confirming the efficacy and safety of this 15-minute outpatient procedure in the management of intermediate and high-grade VUR.[52]

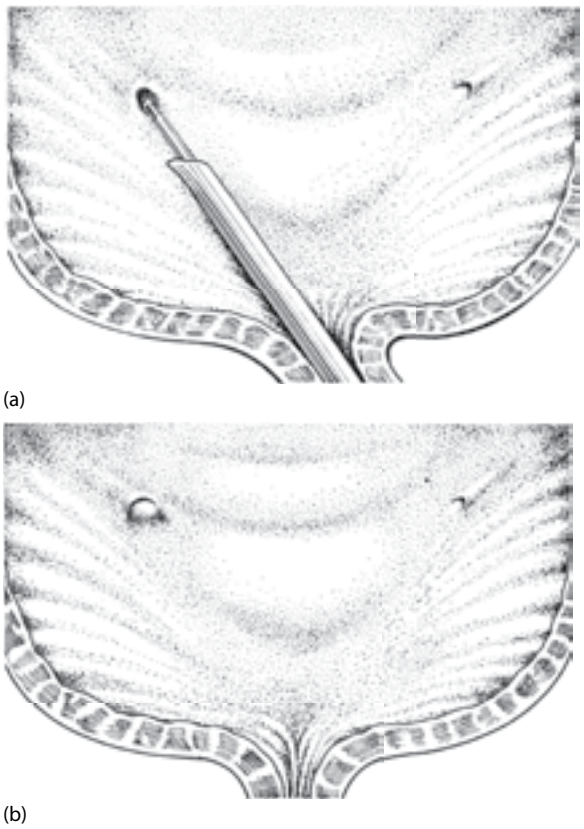

Figure 104.5 Technique of endoscopic subureteric injection: **(a)** site of insertion of needle; **(b)** appearance of ureteric orifice at completion of injection.

Endoscopic subureteral injection of Deflux is excellent first-line treatment in children, with 87% success in high-grade VUR after one injection. This 15-minute outpatient procedure is safe and simple to perform, and it can be easily repeated in failed cases.

Ureteroceles in the newborn

JONATHAN F. KALISVAART AND ANDREW J. KIRSCH

INTRODUCTION

Ureteroceles are congenital, cystic dilations of the terminal, intravesical portion of the ureter. The associated ureteral orifice, often extremely difficult to visualize, may be partially or totally obstructed, resulting in variability in size from small to very large. Ureteroceles can also vary in location from intravesical to ectopic. The use of fetal ultrasonography has improved the diagnosis of ureteroceles; however, they often remain difficult to diagnose and require complete postnatal evaluation when suspected.

PATHOGENESIS

The pathogenesis of the ureterocele remains unclear, although several theories have sought to explain it. Chwalla[1] and Ericsson[2] attributed the ureterocele formation to the persistence of an epithelial sheet (Chwalla's membrane) separating the lumen of the distal portion of the Wolffian duct and the urogenital sinus. Chwalla's membrane is a normal embryologic structure that disappears spontaneously approximately 2 months after conception. If it persists, it can balloon out and form the ureterocele. Stephens,[3] on the other hand, postulates that the terminal ureter becomes involved in the growth of the bladder and undergoes extensive enlargement, resulting in the formation of the ureterocele. Tanagho[4] suggests that the ureterocele forms secondary to local dilatation of the ureteral bud prior to its migration from the Wolffian duct. Tokunaka and colleagues[5] demonstrated poor muscle development in the dome of the ureterocele and suggest that ureterocele formation is based on a segmental embryonic arrest of the development of the most distal portion of the ureter. These theories regarding the pathogenesis of ureteroceles are still only speculations.

Pathological anatomy and associated pathology

Ureteroceles can be associated with the ureter draining the upper moiety of a duplex collecting system or with the ureter of a single system. Duplex-system ureteroceles occur in approximately 85% of diagnosed cases and can vary in size and position. The upper renal moiety is nonfunctional and dysplastic in over 80% of cases.[6,7] Occasionally, ureteroceles are small and well demarcated from the bladder wall, but often, they present as very large subtrigonal masses. The ureterocele may also protrude toward the contralateral ureteral orifice or the bladder neck, causing contralateral ureteral or bladder outlet obstruction. More commonly, the ipsilateral orifice of the ureter draining the lower pole is pushed upward by the distended ectopic ureterocele, shortening the intratrigonal tunnel, leading to reflux and hydronephrosis. On the contralateral side, reflux and secondary hydronephrosis can be seen, likely due to the disruption of the normal trigonal anatomy. Less commonly, reflux can be seen to occur into the ureterocele itself.

Ureteroceles are attached to single collecting systems in approximately 15% of cases, often in males.[6,7] The cystic swelling tends to be asymmetric, with the ureteral orifice located in an eccentric position. The single-system ureterocele is usually smaller in size than the ectopic ureterocele, and the size of the ureterocele is generally related to the degree of obstruction caused by the pinpoint orifice.[8]

Single-system ureteroceles rarely prolapse and cause bladder neck obstruction, and reflux is extremely uncommon. Although the ureter and pelvicalyceal structures are hydronephrotic to varying degrees, function of the renal unit is often preserved.

CLASSIFICATION

In 1954, Ericsson[2] classified ureteroceles into *orthotopic or simple* ureteroceles if the ureter forming the ureterocele ends in a normal site in the bladder or *ectopic* ureteroceles if the ureter ends in an ectopic location. However, confusingly, a simple ureterocele can also mean a ureterocele involving a single system, and an ectopic ureterocele can describe a ureterocele associated with a duplicated system. Stephens[3] classified ureteroceles based on the anatomic location and appearance of the orifice into *stenotic* (narrowed opening found in the bladder), *sphincteric* (an orifice distal to the bladder neck),

sphincterostenotic (a narrowed opening distal to the bladder neck), and a *cecoureterocele* (intravesical orifice with a submucosal extension into the urethra). These traditional classifications, based on the location of the ureteral orifices or on the anatomical description, can be quite confusing. The modern classification system is based on the report of the Committee on Terminology, Nomenclature and Classification of the Urology Section of the American Academy of Pediatrics.[9] It subdivides ureteroceles based on the following:

1. Number of ureters that drain the kidney ipsilateral to the ureterocele
2. Location and extent of the ureterocele
3. Any additional anatomic distortions of the ureterocele resulting from eversion, prolapse, or secondary incompetence or obstruction of the other ureteral orifice or the bladder neck

Thus, a duplex-system ureterocele is when the ureterocele is attached to the upper pole ureter of a completely duplicated collecting system, and a single-system ureterocele is when the ureterocele is attached to a single ureter draining the kidney. If the ureterocele and its orifice are located entirely within the bladder, the term *intravesical* is used, and if the ureterocele and its orifice extend beyond the trigone to the bladder neck or outside of the bladder to involve the urethra, the term *ectopic* is applied. Single-system ureteroceles are generally intravesical, and ectopic ureteroceles are usually associated with the upper pole ureter of a duplex system (Figure 105.1).[10]

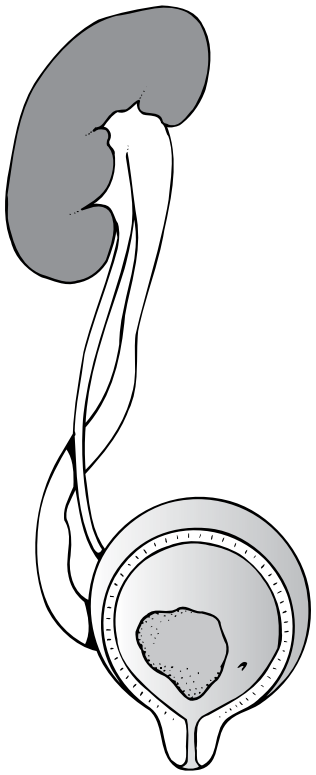

Figure 105.1 Ectopic ureterocele in relation to the upper moiety of a duplex collecting system.

INCIDENCE

The incidence of ureteroceles varies between 1:1,500 and 1:12,000 pediatric admissions, depending on the study,[11,12] and is 1:4000 autopsies.[13] Ureteroceles occur most frequently in females with a 4:1 ratio and are more common in Caucasians.[14] Duplex-system ureteroceles are four to seven times more common in females than in males,[15] and single-system ureteroceles appear to have a slightly male predilection.[10]

There does not appear to be a predilection toward laterality as both kidneys are equally affected[16] and bilateral ureteroceles are found in approximately 10% of cases.[8]

CLINICAL PRESENTATION

The clinical presentation of ureteroceles in infants and children is a febrile urinary tract infection in 39%–73.5% of the cases.[7,17–19] Sepsis, hematuria, urinary incontinence, and/or flank pain can be present. Nonspecific symptoms such as failure to thrive, irritability, urinary retention, or recurrent vomiting should also lead to further investigation of the urinary tract. In cases of severe obstruction and consequent gross megaureter and hydronephrosis, a palpable mass may be present in the abdomen or in the pelvis. Severe electrolyte disturbances, such as hyperkalemia, may occur, and in very rare cases of hyponatremia and hyperkalemia, *pseudohypoaldosteronism* should be suspected.[20]

In baby girls, the ureterocele may prolapse through the urethra and can be seen as an apparent vaginal or vulvar mass (Figure 105.2).

DIAGNOSIS

Ureteroceles can be diagnosed in the antenatal period as part of a screening ultrasound. After the 30th week of pregnancy, the ureterocele may be demonstrated in the fetal bladder (Figure 105.3). More often, however, the antenatal ultrasound performed after the 16th gestational week shows only hydronephrosis. The causative pathology of this hydronephrosis can generally only be established by immediate

Figure 105.2 Prolapsing ureterocele in a female newborn.

Figure 105.3 Antenatal ultrasonography. Ureterocele in the fetal bladder as seen in the 30th gestational week.

postnatal investigations. These investigations have traditionally consisted of ultrasonography, voiding cystourethrogram (VCUG), and cystoscopy. In addition, Dimercaptosuccinic acid (DMSA), Diethylenetriaminepentaacetic acid (DTPA), Mercaptoacetyltriglycine (MAG3) renal scintigraphy, or magnetic resonance urography (MRU) should be used to detect renal cortical defects, and evaluate renal function and

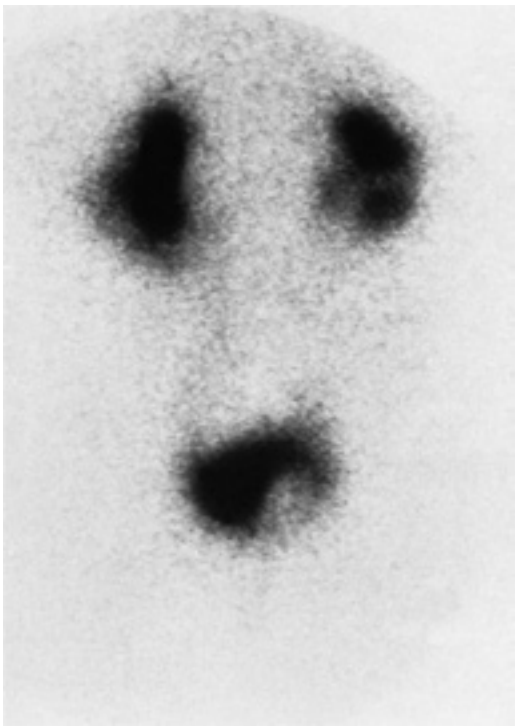

Figure 105.4 Isotope scan (DMSA) demonstrating the ureterocele (uptake defect in the bladder) and the non-function of the upper renal moiety.

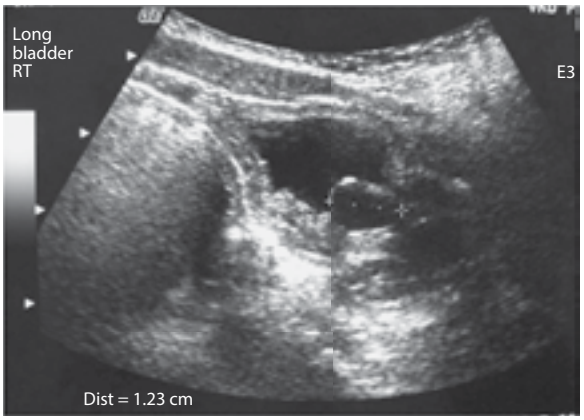

Figure 105.5 Postnatal ultrasonography. Ureterocele within the bladder.

the degree of ureteral obstruction (Figure 105.4). Although inferior in many ways, Intravenous Urogram (IVU) may be used in cases where other imaging modalities are unavailable.

Ultrasonographic findings are of a cystic mass within the bladder, often with dilatation of the associated ureter and pelvicalyceal structures (Figure 105.5). VCUG shows a filling defect within the bladder varying in size and position. The ectopic ureterocele is seen as a filling defect placed eccentrically along the bladder wall extending into the bladder neck or into the posterior urethra. The intravesical ureterocele is generally surrounded by contrast medium demonstrating most of its circumference. If the images are taken when the bladder is full, the ureterocele may evert, mimicking a bladder diverticulum (Figure 105.6).

With the VCUG, reflux into all renal units can also be assessed. Studies have estimated that 50% will have reflux into the ipsilateral lower pole, 25% into the contralateral ureter, and 10% into the ureterocele-bearing ureter.[21]

MRU has also been used to diagnose ureteroceles both in fetal life and in infants with a sensitivity of 89%–100%. The advantages of MRU include anatomic images of both the upper and lower tracts, and with the correct sequences, functional data of the upper tract can also be delineated.[22–25] This information can be useful both in decision making and in surgical planning (Figure 105.7).

Once the diagnosis is suspected based on imaging, cystoscopy can confirm the diagnosis and help with surgical planning.

TREATMENT

Ureteroceles are often complex anomalies. Although considerable controversy still exists regarding the best treatment, the final aims of the surgical management of the ureterocele are to relieve obstruction, prevent urinary infection, prevent or correct vesicoureteral reflux, and preserve renal function. The latter goal may be considered secondary as the upper pole moiety serving the ureterocele is often dysplastic with marginal function.

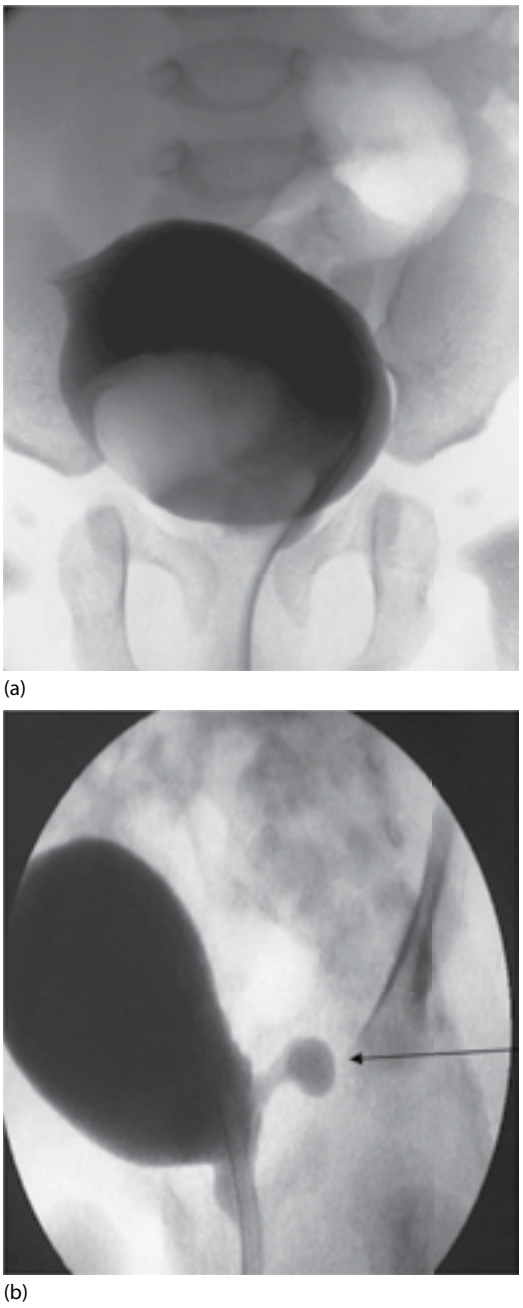

Figure 105.6 Voiding cystourethrogram (VCUG) showing **(a)** ureterocele in the bladder and **(b)** eversion of the ureterocele with filling of the bladder (arrow).

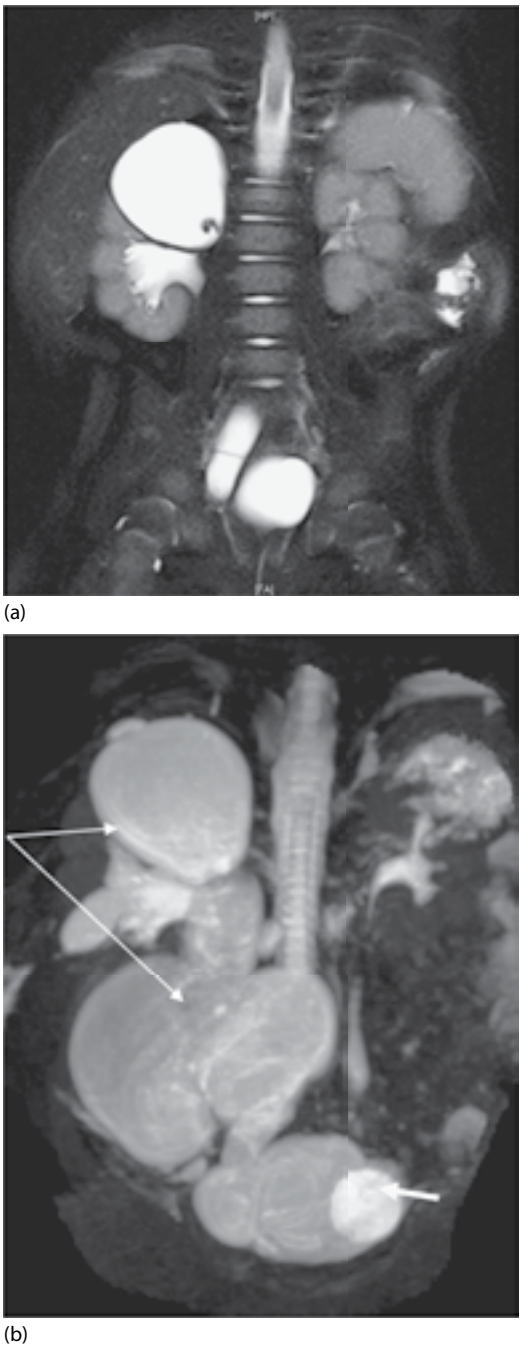

Figure 105.7 T2-weighted Magnetic resonance urography (MRU) showing **(a)** the dilated upper pole associated with the ectopic ureterocele and **(b)** the characteristic appearance of the ureterocele (thick white arrow) with the associated dilated renal upper pole and ureter (thin white arrows).

As a result of these goals, four aspects have to be taken into account in the planning of the correct surgical treatment[25]:

1. Degree of renal dysplasia and its resulting loss of renal function
2. Presence of reflux into the ureterocele-bearing ureter, the ipsilateral ureter, and/or the contralateral ureter
3. Altered trigonal anatomy as well as the weakness of the detrusor muscle backing the ureterocele
4. Degree of obstruction caused by the prolapsing or ballooning ureterocele

A standardized approach is probably impossible, and it seems reasonable to individualize the management according to the aspect of each particular case.[26]

Conservative management

Patients meeting specific criteria have been successfully managed with prophylactic antibiotics only. These criteria are as follows:

1. Either a well-functioning renal moiety associated with the ureterocele or a completely nonfunctioning renal unit associated with the ureterocele
2. No evidence of obstruction on functional renal imaging
3. No other pathology (i.e., bladder outlet obstruction)

Sixty to seventy percent of these highly selected patients managed conservatively had resolution of reflux and hydronephrosis,[27,28] showing that, in this highly selected group, surgery may be avoided. However, the long-term potential sequela of small persistent ureteroceles, such as urolithiasis and infection, have not been evaluated.

Endoscopic puncture or incision

With improvements in urologic endoscopic technology, a more conservative approach in the surgical management of the ureterocele is feasible. Several authors have demonstrated the advantages of the endoscopic incision or puncture of ureteroceles in the preservation of renal tissue,[29–32] and in the case of the septic or acutely ill child with an obstructing ureterocele, endoscopic puncture should be considered to be the first-line treatment. This procedure can be performed with the patient under general or regional anesthesia, on a same-day surgery or outpatient basis.[33] Satisfactory postoperative urinary tract decompression has been reported in 85%–100% of cases of endoscopic decompression,[33–35] and recovery of renal function following endoscopic puncture or incision has been reported.[33,34]

Several techniques of endoscopic puncture or incision of ureteroceles exist, but the most common technique consists of a small 2–3 mm incision or puncture made just above the distal junction of the ureterocele with the bladder using a Bugbee electrode[36] or a sharp electrode[29] through a pediatric cystoscope (Figure 105.8). This avoids leaving a flap of ureterocele that might obstruct the bladder outlet and works to preserve a flap valve of the collapsed ureterocele. All these techniques bear the risk of interfering with the structures of the lower pole orifice, and an attempt to visualize the lower pole orifice should be made to prevent such damage. Postincision imaging should be performed to detect reflux in all renal segments and to determine the need for further surgery. A second puncture should be considered in cases where a large ureterocele persists postoperatively and the degree of hydroureteronephrosis on ultrasound remains unchanged or worsened. In the future, even less invasive methods of puncture may be available such as pulsed focused ultrasound.[37]

Controversy still exists regarding the advantages of the endoscopic puncture or incision of ureteroceles as a "first-stage" treatment, principally due to the high association of postoperative reflux and secondary operations.[21,38–40,41] Surgeons in favor of the endoscopic puncture or incision first-stage treatment in neonates with ureteroceles suggest the following:

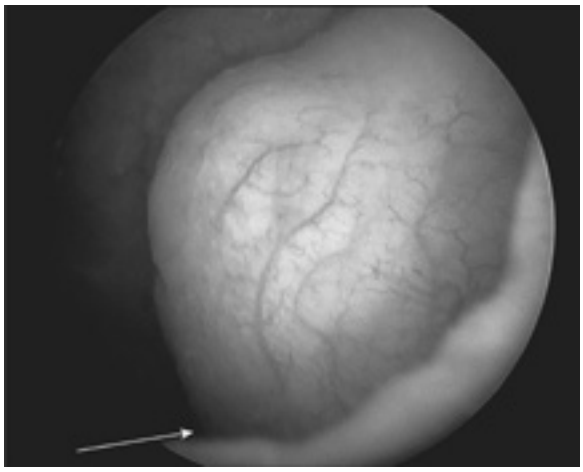

Figure 105.8 Cystoscopic view of an ureterocele. The arrow indicates the target for endoscopic puncture. (Image courtesy of Dr. Edwin Smith.)

1. Approximately one-third of these patients will be definitively treated by this technique.
2. Early renal and ureteral decompression will allow improvement or stabilization of renal function, as well as a decreased risk of pyelonephritis.
3. It allows for a delay in definitive surgical correction, if necessary, and a technically easier operation after the neonatal period due to bladder growth and decreased distention of the affected ureter.[21,29,30,38,39,41–43]

A recent meta-analysis found that, among patients undergoing endoscopic puncture of their ureterocele, risk factors for repeat surgery included an ectopic versus an intravesical ureterocele (Relative Risk, 2.78), ureteroceles draining the upper pole of a duplex system versus those draining a single system (RR, 3.93), and patients with preoperative reflux versus those without reflux (RR, 1.56).[44,45] Thus, the anatomy of each individual patient needs to be taken into account prior to any attempt at endoscopic puncture as a primary treatment.

Duplex-system ureteroceles

For the treatment of duplex-system ureteroceles, four definitive surgical options are available:

1. Heminephrectomy with partial or total ureterectomy, allowing the ureterocele to collapse (upper-tract approach)
2. Excision or marsupialization of the ureterocele, reconstruction of the bladder, and reimplantation of the ureter(s) (lower-tract approach)

3. Combination of heminephrectomy and excision or marsupialization of the ureterocele (combined upper- and lower-tract approach)
4. Ureteroureterostomy (UU) to bypass the obstructed lower ureter and allow for adequate drainage of the upper pole

Ureterocele excision or marsupialization

The traditional open surgical approach involves the complete excision of the ureterocele with reconstruction of the bladder and bladder neck to create a functional bladder neck mechanism. Potential problems with this approach involve injury to adjacent structures, primarily the bladder neck; sphincteric mechanism; or creation of a vesicovaginal fistula. An alternative involves the marsupialization of the ureterocele, which leaves the floor of the ureterocele intact and adhered to the bladder mucosa. This prevents the potential injury to the surrounding structures due to the decreased dissection needed. One study has found no statistical difference between these two techniques.[46]

Procedure

Using a modified Pfannenstiel incision, the skin and the anterior rectus sheath are opened transversally. The recti are bluntly separated in the midline, and the bladder is well mobilized laterally. Over the bladder dome, the peritoneal covering has to be carefully stripped off, avoiding entry into the peritoneal cavity.

The previously filled bladder is incised longitudinally, taking care to avoid injury to the bladder neck. The lower end of the incision can be secured with a holding stitch to prevent tearing into the bladder neck or urethral sphincter and to make for easy identification when closing. The edges of the incised bladder are suspended and held open with holding sutures over the Denis-Browne ring retractor. Several sponges are placed into the superior bladder (the exact number varies depending on the size of the bladder), and the cranial blade is positioned inside the bladder dome over the sponges, pulling it upward and forward, exposing the trigonal area. The ureterocele, the orifice of the lower renal pole ureter, and the contralateral ureter are visualized (Figure 105.9). Each ureter is catheterized with an infant feeding tube or a ureteral catheter. Stay sutures are placed in the dome of the ureterocele, and the urothelium is incised in an elliptical fashion (Figure 105.10a,b).

If the ureterocele is to be completely excised, a dissection plane between the wall of the ureterocele and the urothelium and the detrusor muscle is found, and the ureterocele is dissected off the urothelium (Figure 105.10c). Once the ureterocele is freed completely, the remaining intramural ureter is mobilized as with a standard intravesical ureteral reimplantation (Figure 105.10d). If the ureterocele reaches into the bladder neck or the posterior urethra, this procedure can be extremely difficult to perform, and care has to be taken not to damage the urethral sphincter or its nerve supply. Once the ureterocele is resected, its backing detrusor muscle must be carefully reconstructed using resorbable monofilament sutures (Figure 105.10e). This is to minimize diverticulum formation.[47] In girls, damage to the underlying vagina and, in boys, damage to the ipsilateral vas deferens has to be avoided during this procedure.

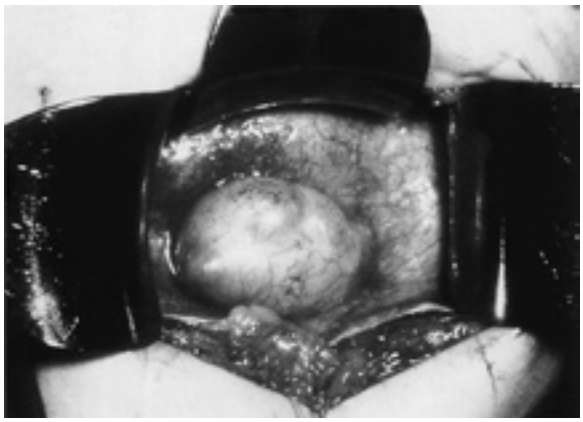

Figure 105.9 Operative treatment: intraoperative findings of a duplex-system ectopic ureterocele.

Alternatively, the ureterocele can be marsupialized by excision of the anterior and lateral walls of the ureterocele using cattery. This leaves the posterior wall in continuity with the detrusor muscle behind it. The edges of the ureterocele are then reapproximated to the surrounding mucosa using absorbable sutures.

At this stage, the ureters are reimplanted according to Cohen's technique,[48] creating a cross-trigonal submucosal tunnel. Stenting of the reimplanted ureter can be performed according to the surgeon's preference. We generally do not stent the ureter unless there is a specific reason to, i.e., a solitary kidney, an abnormally small ureter, etc.

The bladder is then closed in a standard two-layer technique using resorbable sutures. The bladder is drained with a transurethral catheter. The urethral catheter is generally removed between 1 and 7 days after surgery depending on surgeon preference. Prophylactic antibiotics are administered perioperatively and are continued until absence of reflux is confirmed with postoperative imaging.

Heminephroureterectomy

This procedure can be performed in the traditional open technique, laparoscopically, or using a robot-assisted technique. The laparoscopic partial (or polar) nephrectomy has had good results reported but is widely considered to be one of the hardest laparoscopic procedures to perform.[49] The robot-assisted technique removes many of the technical barriers to the laparoscopic approach. The open and robot-assisted surgical approaches will be covered here.

Procedure

The open upper pole nephrectomy is performed through a flank incision just off the tip of the 12th rib. The incision is extended to a length of 3–4 cm.

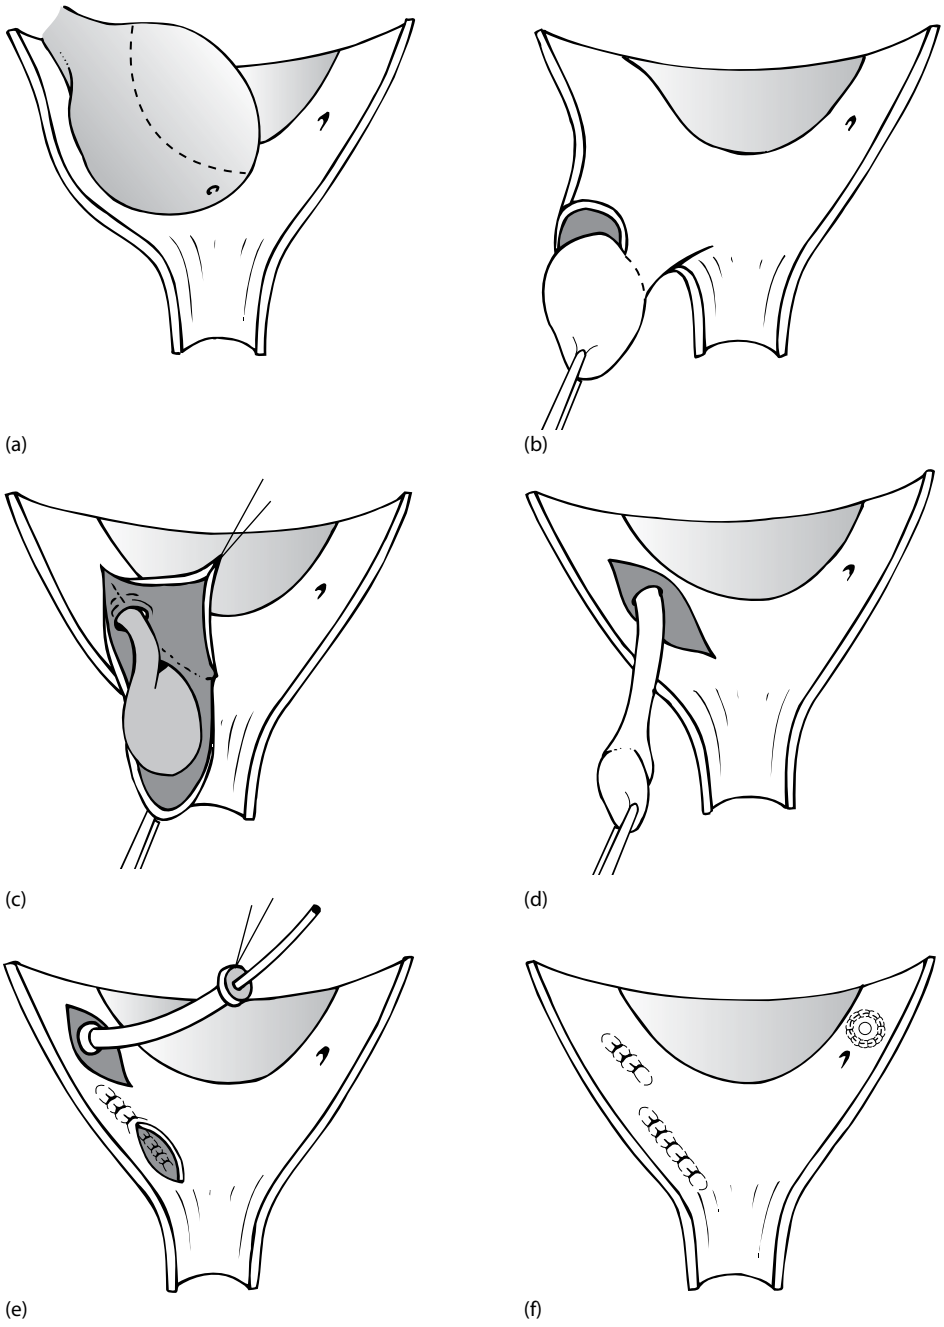

Figure 105.10 Operative treatment—ureterocele enucleation. **(a)** Planned elliptical incision on the dome of the ureterocele. **(b)** The ureterocele is held with stay sutures, and the elliptical incision is performed. **(c)** A plane between the wall of the ureterocele and the urothelium or the detrusor muscle is dissected. **(d)** The intramural ureter of the upper moiety is mobilized, taking care not to damage the lower moiety ureter. **(e)** Reconstruction of the detrusor muscle backing the ureterocele and the urothelial defect. **(f)** The lower moiety ureter is reimplanted according to Cohen's technique, creating a transverse suburothelial tunnel.

The muscle layers are incised using cautery down to the level of the retroperitoneum. The retroperitoneum is entered, and the peritoneum is gently dissected anteriorly. The wound is held open with a retractor. Gerota's fascia is exposed and opened posteriorly.

In the robot-assisted technique, an 8.5 or 12 mm robotic camera port is placed in the umbilicus, and two additional 5 or 8 mm ports are placed with one in the midline superior to the umbilicus and one in the midline or just lateral to it inferior to the umbilicus. The colon is reflected medially along the white line of Toldt to expose the ureters.[50]

In both techniques, the upper pole ureter can then be identified, generally quite easily due to its size. The upper pole ureter is dissected free from the surrounding tissue. The lower pole ureter needs to be identified and dissected free, being careful to leave a sufficient amount of periureteral

tissue in place to avoid devascularization. The dilated upper pole ureter is then followed up toward the renal hilum. It is brought under the renal vessels, being careful not to injure them. There is often a separate renal artery to the upper pole segment, which needs to be identified, isolated, and ligated. Once this is accomplished, the ureter can be followed to the upper pole segment, which can be dissected free from the remainder of the renal parenchyma. There is generally a renal groove between the upper and lower pole segments, which can assist in the dissection. The different color and consistency of the dysplastic upper renal pole can be of additional help in the anatomical definition of the two segments (Figure 105.11a). Alternatively, the upper pole system can be entered and can be dissected away from the lower pole from the inside of the collecting system. Extreme care must be taken to preserve the lower renal vasculature.

It is important to remove the entire pelvicocalyceal structures of the upper renal pole and to carefully inspect the remaining kidney for opened lower pole calyces, which need to be closed meticulously with absorbable sutures.

Once hemostasis is achieved, the renal capsule is approximated and sutured with absorbable sutures (Figure 105.11b). Hemostatic agents such as Floseal, Tisseel, or Surgicel can be of additional help to control hemostasis.

Heminephrectomy is now accomplished without having interrupted the circulation to the lower moiety.

Following this procedure, the upper pole ureter is dissected toward its distal portion as far as possible. The dissection line is kept close to the diseased ureter in order not to disturb the lower pole ureter blood supply. If the ureter refluxes, it is ligated and transected, but if it is obstructed, it is transected without ligation to prevent infection.

Once the heminephroureterectomy is completed, a drain can be placed according to surgeon preference, and the muscular layers are approximated using continuous 3-0 or 4-0 resorbable sutures. The subcutaneous tissues are approximated and the skin closed with a subcuticular suture.

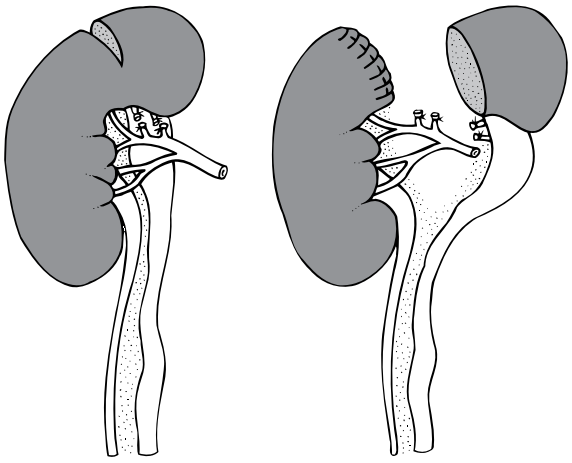

Figure 105.11 Operative treatment—heminephrectomy. **(a)** Transverse resection of the affected upper renal moiety of a duplex system. **(b)** After hemostasis, the renal parenchyma and the renal capsule are closed, often over a bolster of hemostatic material.

Ureteroureterostomy

UU is increasingly being used to repair duplex systems with reasonable function of the upper pole and relatively equal calibre of ureters, although it has been shown to be effective in systems with any degree of function and ureteral size.[51] The UU enjoys the advantage of avoiding the renal vasculature and lower pole of the kidney and the potential for injury to these structures. The primary disadvantage is that the normal, lower pole ureter is involved in a surgery that has the potential to cause damage to it. The UU can be performed using a straight laparoscopic technique, but only the open and robot-assisted techniques will be described here.

Open procedure

Once under anesthesia, cystoscopy is generally performed, and a stent is placed up the normal-calibre, lower pole, "recipient" ureter. This helps with identification and to stent the ureter at the end of the case.

The skin and the anterior rectus sheath are opened transversally using a modified Pfannenstiel incision. The recti are bluntly separated in the midline, and the bladder is well mobilized laterally on the affected side. Over the bladder dome, the peritoneal covering has to be carefully stripped off, avoiding entry into the peritoneal cavity. The ureters are identified in the retroperitoneum and isolated and gently separated from one another, being careful to avoid devascularization of either ureter. The upper pole ureter ("donor" ureter) is transected as close to the bladder as possible and the stump irrigated out. If the ureter refluxes, the stump should be tied off. The recipient ureter is opened in an anteromedial ureterotomy, and the anastomosis is completed using absorbable suture. The stent can either be left in the recipient ureter or be brought across the anastomosis going from the distal recipient ureter to the proximal donor ureter. A drain is placed, and a bladder catheter is left in place, generally overnight. The stent is left in place for 4–6 weeks.

Robot-assisted laparoscopic procedure

In the robot-assisted technique, cystoscopy and stent placement are performed as in the open technique. Three ports are placed with an 8.5 or 12 mm robotic camera port placed in the umbilicus. Two additional 5 or 8 mm instrument ports are placed in the midclavicular line on either side, often 1–2 cm below the umbilicus.

The ureters are identified transperitoneally in the area of the iliac vessels. They are exposed and mobilized approximately 2–3 cm in either direction. The recipient ureter is identified (the stent can assist with this) and is mobilized away from the donor ureter, being careful not to devascularize either ureter. The donor ureter is identified and divided as far distal as possible with the stump sutured or tied off

if reflux is present (Figure 105.12a). The anastomosis of the ureters is completed in an identical fashion to the open procedure (Figure 105.12b), again with the stent either left in the recipient ureter or placed across the anastomosis.[50,52]

Percutaneous drainage

Percutaneous drainage of systems with ureteroceles is generally only indicated in cases in which the patient is acutely ill and endoscopic puncture is not an option due to small urethral size or the inability to undergo anesthesia.

SUMMARY

Ureteroceles are a fairly common urologic finding. The management of the ureterocele can be quite complex and needs to be individualized for the patient and his/her condition as well as the findings of imaging and functional studies.

Posterior urethral valves

PAOLO CAIONE AND MICHELE INNOCENZI

INTRODUCTION

Posterior urethral valves (PUVs) are the main cause of urethral obstruction in newborns and infants that continues to be a significant cause of morbidity and mortality in pediatric-age patients.[1,2] In males, children born with bladder obstructive uropathy and renal dysplasia represent the single largest group undergoing renal dialysis and transplantation under 5 years of age. End-stage renal disease develops in a significant proportion, varying from 30% to 42%.[1] In 2003, the ItalKid Project, which consists of a prospective population-based registry assessing the epidemiology of chronic renal failure (CRF) in pediatric age on the basis of 1197 patients recruited in 10 years, showed that renal hypodysplasia with identified congenital uropathy was the most common cause of CRF (43.6%): in this group, PUVs were second only to vesicoureteral reflux (VUR), accounting for 23.8%.[3]

HISTORICAL NOTES

Congenital obstruction of posterior the urethra has been recognized for almost 200 years, as the earliest description of this condition in infants was by an Italian anatomist, Giovanni Battista Morgagni, in 1717.[4] Langenbeck[5] described infravesical urethral obstruction in 1802 in his monograph on stone disease, and a few years later, in 1832, Velpeau[6] utilized for the first time the term *valves*. Subsequently, many reports of posterior urethral obstruction can be found in the literature. The most important contribution to define the anatomical aspects of valves was made by Hugh Hampton Young in 1919[7] and 1929.[8] Young was the first to describe clearly the features of PUV. The description included the first classification of this entity based on his initial report on 12 patients, and a review of the literature.[7] The Young classification distinguished congenital obstruction of the posterior urethra on three types of valves (Type I, Type II, Type III), which he described in detail (Figure 106.1).[9] In more recent years, some criticism arose from the analysis of Young's original work, revealing different opinions from his conclusions.[10–13] A large contribution to a better anatomical definition of PUV and urethral diaphragm was given by Hendren and more recently by P. A. Dewan and coauthors,[14,15] who identified the morphological evidence of the congenital membrane obstructing the male posterior urethra (see section titled "Classification"). Anyway, Young's classification, although not anatomically precise, is well known worldwide and still utilized currently.

EPIDEMIOLOGICAL DATA

The epidemiology of PUV is uncertain to define, as most authors believe that only those with typical appearance on voiding cystourethrograms (VCUGs) should be counted. The incidence of PUV often is reported as 1:5000 to 1:8000 infant males,[14–16] 1 child in 25,000 live births,[16] but this value seems to be underestimated.[17] The point is that the true incidence of congenital posterior urethral obstruction is difficult to ascertain.

The lesion could be more common than previously thought: this is due to the fact that the widespread use of prenatal and postnatal ultrasonography and of the VCUG during the recent few decades led to the recognition of a higher number of congenital valves, diaphragms, or strictures on the male posterior urethra, not always recognized as classic valves.

Moreover, at endoscopy or at VCUG, "mild" or "minor" forms of inframontanal *plicae* or mucosal folds, responsible for partial or little urinary outflow, are nowadays a more common observation in male children and infants, as a consequence of widespread use of cystourethroscopy. So, the full spectrum of congenital posterior obstruction is probably twice as frequent as previously thought.[18]

EMBRYOLOGY

Obstruction of the male posterior urethra is a congenital abnormality, which is considered to have no genetic basis and no pattern of inheritance. There is no agreement as regards

the true embryogenesis. It has been argued that posterior valves could originate from an abnormality of development during formation of the urogenital sinus.[19] Livne et al.[20] proposed that the valves' embryogenesis arises from maldevelopment of the urethrovaginal folds, appearing at 11 weeks' gestation, from the *plicae colliculi* diverging from the distal end of the *verumontanum* (mesonephric Wolffian duct). Field and Stephens[21] believed that valves could be vestiges of the receding Wolffian ducts, which migrated posterolaterally to converge on the posterior wall of the urethra, creating the inferior urethral crests. Fusion of these folds anteriorly would explain the formation of a membranous obstruction with a posterior deficit, as described by Dewan.[15] A detailed review of the literature has recently been focused by Krishman and coauthors,[22] better elucidating the precise origins regarding the anatomy, classification, and embryology of PUV. Anyway, the embryological development of the congenital posterior urethra obstruction in male fetuses and infants remains uncertain. With the advent of more accurate imaging techniques, such as ultrasonography, VCUG, and fetal/infant magnetic resonance imaging (MRI), the obstructive membranes of the posterior male urethra are now better defined. It is hypothesized that the severity of the congenital diaphragm obstructing the urethra is variable, consistent with the differential clinical presentation of PUV. In some cases, the membrane is only partially obstructing, whereas in other situations, it may be totally obstructing, as in infants with severe renal sequelae. When a feeding tube or catheter is passed in the newborn urethra, the membrane could be ruptured ventrally, modifying the appearance into Young's classic valves.[22]

CLASSIFICATION

Young and colleagues in 1919 divided PUV into Types I, II, and III, based primarily on autopsy findings.[7] Young described Type I valves as sails or strong plicae colliculi, which extend distally from either side of the verumontanum to attach to the anterolateral walls of the urethra; Type II valves are folds that arise from the verumontanum and pass proximally toward the bladder neck, where they divide into finlike membranes; Type III valves are diaphragms with a central perforation located distal or proximal to the verumontanum, but not attached to it (Figure 106.1).

Most authors agree that Young's classification is incorrect. In particular, the existence of Type II valves has been questioned, as these plicae should be considered as normal mucosal folds.[15–17]

The Type I valves are the most commonly recognized. The clinical description of a valve with two separate leaflets is derived from autopsy specimens in which the urethra is laid open by cutting through the anterior wall. However, when viewed endoscopically, it is seen to be a single structure originating from the inferior margin of the verumontanum, the lateral folds fusing anteriorly to form a slit-like aperture. Dewan and colleagues, in accurate endoscopic studies, demonstrated that the commonly defined PUVs are represented by a single membrane with a posterior defect, distal to the verumontanum but connected to it by mucosal folds. Dewan proposed the term "congenital obstructive posterior urethral membrane" (COPUM) to define this lesion.[14,15,23]

Type III valves are considered very uncommon, and they represent a severe form of urethral obstruction.[16] In a review of cystoendoscopies of boys with urethral obstruction, Dewan described a fibrous membrane without attachment to the verumontanum, with a central defect below the verumontanum in the bulbar urethra.[14,15] These lesions are known as Cobb's collar,[24] Moormann's ring,[25] or congenital bulbar urethra stricture, but should be distinguished from the COPUM or misnamed Type III valves.[23]

In conclusion, nowadays we consider PUV as a spectrum of anatomical and pathological entities, presenting different severities of urinary outflow obstruction and having probably only two structural features:

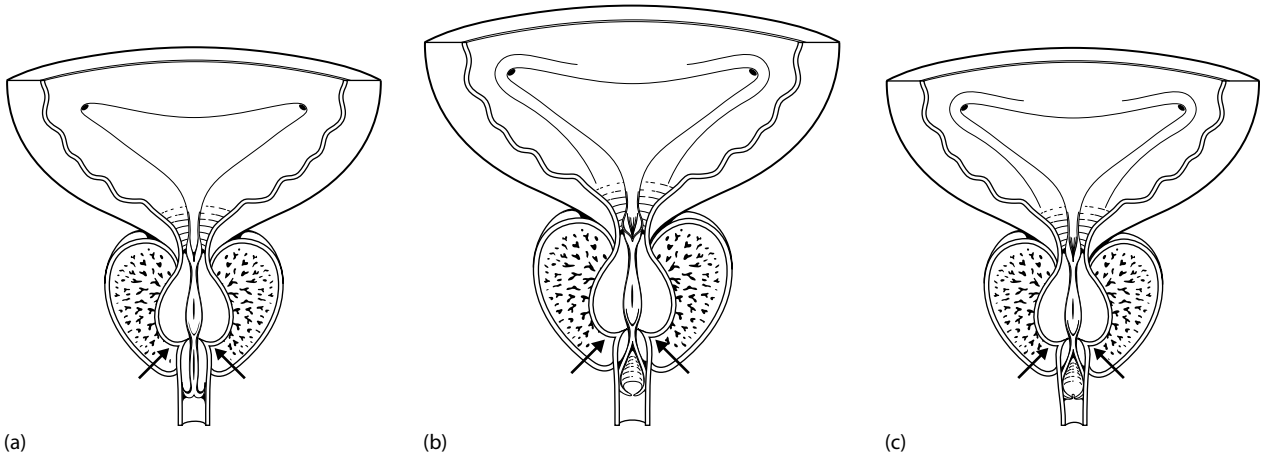

Figure 106.1 **(a, b, c)** Posterior urethral valves: The original classification proposed by Young in 1919 in 3 types. (From Macpherson RI et al., Posterior urethral valves: An update and review, *Radiographics* 1986; 6(5):753–791. Young HH and McKay RW, Congenital valvular obstruction of the posterior urethra, *Surg Gynecol Obstet* 1929;48:509. Waterhouse K and Hamm FC, The importance of urethral valves as a cause of vesical neck obstruction in children, *J Urol* 1962;87:404.)

1. A membrane at the level of the posterior urethra distal to the *verumontanum*, with connecting folds and a posterior defect (COPUM)
2. A fibrous membrane in the bulbar urethra with a central defect (Cobb's collar)

PATHOPHYSIOLOGY OF PUVs

Congenital posterior urethral obstruction interferes with all the lower and upper urinary tract, causing significant anatomical and functional changes. In pediatric urology, PUV could represent a severe congenital uropathy, with lifelong consequences.

Valves of the posterior urethra represent a spectrum of lesions within the male urethra, grouped under the more extensive term *COPUM*.[15] The macroscopic appearance has been described in the preceding section, "Classification." The severity of the obstruction is varying from small folds without obstruction to unyielding and hard membranes with a small deficit, causing a high degree of outlet obstruction.[26] The valves cause a mechanical and functional obstruction in the urethral conduit, leading to sequential secondary pathological changes. The heaviness of the secondary pathological changes in the upper urinary tract will depend on the degree and timing of the primary obstruction.

Proximally to the obstructive valves, high back pressure prenatally determined is responsible for significant changes in the anatomical appearance. The prostatic urethra is enlarged and elongated, and the *verumontanum* is much more evident; the posterior aspect of the bladder neck is very pronounced, as consequence of muscular hypertrophy, and it could cause impaired bladder emptying also after urethral disobstruction.

The severity of the pathological changes in the urethral and bladder structures and secondarily in the upper tract depends on the degree and timing of the primary urethral obstruction, such as variable morphological expression of the same embryological abnormality, which is considered to have onset very early during the embryological life (16th–18th week of gestational age).[22]

SECONDARY CONSEQUENCES

Secondary pathology on bladder and upper urinary tract

Not only does the posterior urethra dilate and elongate secondarily to the congenital urethral obstruction, but also, the bladder, the ureter, and the kidneys will present significant structural and functional consequences.

Bladder secondary changes

The congenital urethral obstruction is responsible for significant changes in the bladder reservoir, with consequences also in the upper urinary tract and in the renal parenchyma. These changes may persist, although the primary urethral obstruction could be fully solved. As the valve's onset is very early during the fetal life, the abnormal condition of high endoluminal pressure and overdistension of the urinary structures leads to a pathological development and dysfunctional activity of the entire urinary tract and of the renal parenchyma.[24] Experimental studies on fetal lambs demonstrated the induction of renal parenchyma dysplasia and significant histological and functional bladder changes.[27] Bladder dysfunction may present a variety of different pictures, changing throughout the years, before and after puberty.[28]

Macroscopically, the bladder wall presents trabeculations as a consequence of hypertrophy of the muscular components and of the high-pressure regimen. Histologic studies of the bladder wall have shown increased collagen and connective tissue elements within the muscular cells. The collagen/muscular ratio could be increased with reduced muscular components of the bladder wall. The overall structural and functional changes of the bladder, which persist after urethral obstruction release, were named *valve bladder syndrome*.[29]

Ureteral pathology

Dilatation of one or both ureters is often seen in newborns or infants presenting PUV. Ureteric dilatation may be due to vesicoureteric reflux, vesicoureteric junction obstruction, or inefficient ureteric drainage secondary to high vesical pressures. These changes may persist following valve removal,[30] and the ureters may remain enlarged and tortuous, with thickened and rigid walls (Figure 106.2).

Vesicoureteric reflux

Reflux is frequently associated with PUV. It has been reported in 19%–78% of children[31,32] and is thought to be due to a high-pressure regimen in the prenatally obstructed bladder (Figure 106.3). Once the urethral obstruction has been resolved, a significant proportion of patients are expected to have resolution of their reflux.[33] Thus, a conservative approach to VUR

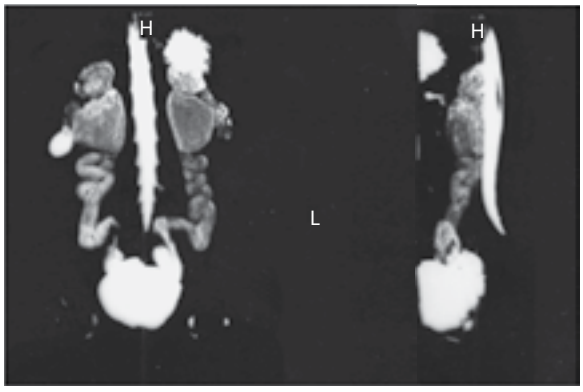

Figure 106.2 MRI of urinary tract in a boy, aged 5 years, born with PUV ablated shortly after birth: The pyelocaliceal system remains bilaterally dilated, with ureters enlarged and tortuous.

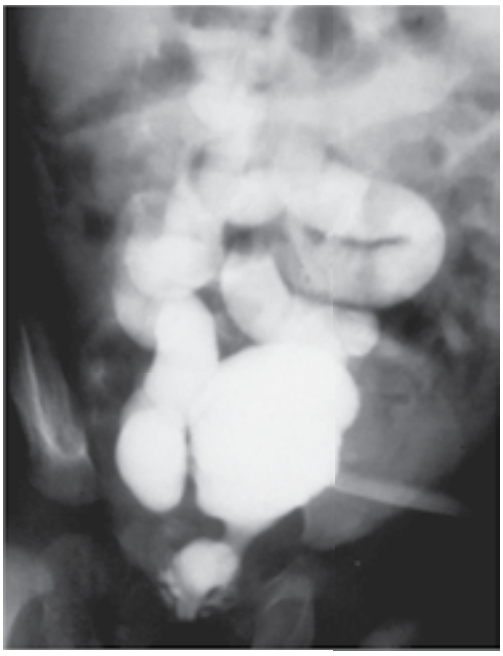
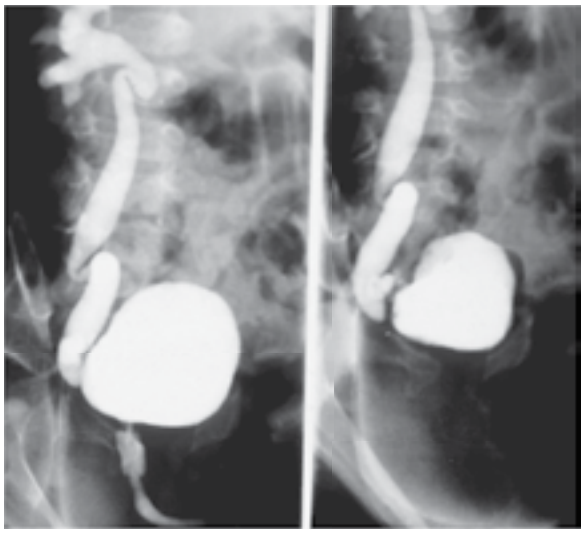


(a)



(b)

Figure 106.3 **(a)** VCUG at birth: Gross bilateral VUR with enlarged trabeculated bladder presenting congenital posterior urethra obstruction, before valve ablation. **(b)** VCUG of the same patient at 4 years of age: Normalization of the bladder and urethra outline, with persisting right VUR.

in children with previous valves or diaphragm on posterior urethra is strongly recommended in infancy and early childhood. The incidences of bilateral and unilateral reflux are almost equal; however, bilateral reflux and posterior urethral obstruction denotes a more severe disease with higher grade of renal parenchymal involvement and risk of CRF.[33]

"VURD" syndrome

John Duckett and coauthors focus on the protective factors in PUV, pointing out that unilateral reflux denotes less severe disease, although the VUR is usually high grade and ipsilateral renal parenchyma is very damaged and dysplastic.[34] In fact, in such cases, the contralateral side is protected by the "pop-off" mechanism that keeps bladder pressures low.[34,35] The kidney on the side affected with reflux is usually nonfunctioning as a result of dysplasia (Figure 106.4). VUR and renal dysplasia in posterior urethral obstruction could be a primary event due to abnormal location of the ureteric bud arising from the Wolffian duct. More probably, the pathogenesis of unilateral renal dysplasia in the "vesicoureteral reflux and dysplasia" (VURD) syndrome, unilateral VURD, is due to the high-pressure regimen of the upper urinary tract, started very early during the fetal life, with consequent impairment of the renal parenchymal maturation.[35]

Renal dysplasia and hydronephrosis

Renal damage is very frequent in PUV, and it can be attributed to a variety of reasons:

1. Primary renal dysplasia
2. Renal dysplasia induced by early intrauterine bladder outlet obstruction, VUR, or ureterovesical obstruction
3. Postnatal urinary tract infection
4. Persistent bladder dysfunction

The association between renal dysplasia and hydronephrosis can be seen as consequence of severe obstructive posterior valves or urethral diaphragm. Renal dysplasia is typically associated with abnormal histology and is not reversible. Hydronephrosis and stasis secondary to obstructive uropathy has normal renal histology and is reversible with treatment.

On the other hand, Hoover and Duckett[35] described the frequent association of posterior urethral obstruction, reflux, and renal dysplasia, suggesting a common embryological error. Henneberry[36] and Stephens proposed that renal dysplasia associated with posterior urethral obstruction is not secondary to reflux or high pressures, but is a primary embryologic malformation that is the result of an abnormal position of the primitive urethral bud.

Early bladder outlet obstruction as in PUV can also produce impaired tubular function. Pediatric nephrologists and urologists from the Great Ormond Street Children's Hospital in London observed that defective urine concentration occurs in as many as 60% of boys with urethral obstruction and is severe in 15%.[37] The resultant concentrating defect causes high urinary output and sodium loss, and the severe polyuria carries a risk of dehydration and electrolyte imbalance. Furthermore, high urine output may increase the overload of work of the lower tract and enhance the bladder dysfunction, causing incontinence and further renal damage in the attempt of obtaining dryness in toilet-trained boys and adolescents.[30] This clinical picture was named valve bladder syndrome.[38]

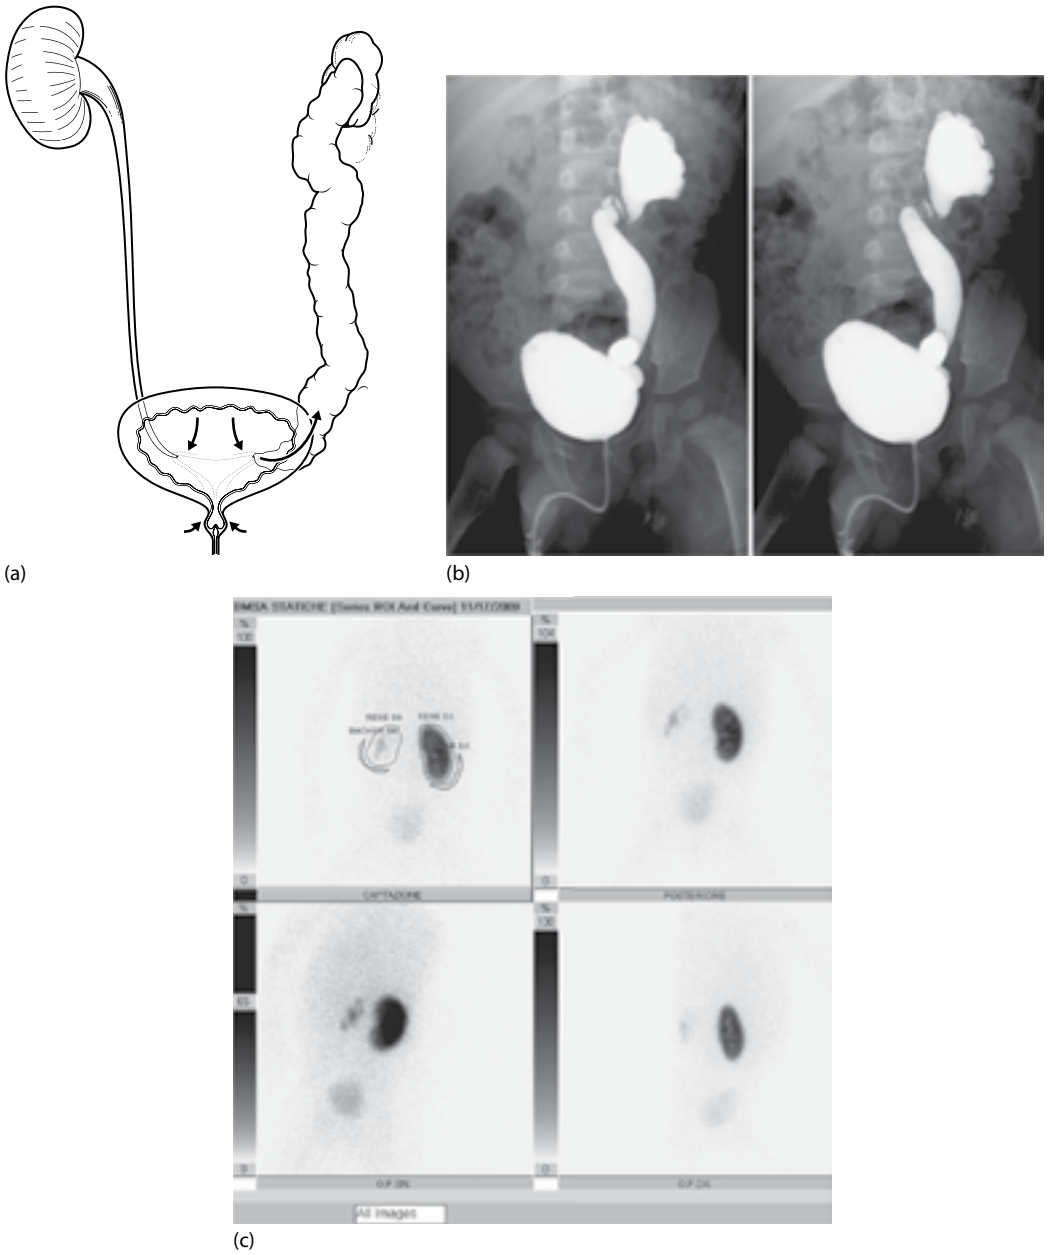


Figure 106.4 **(a)** The "VURD" syndrome (valve, unilateral reflux, dysplasia) as a protective factor for the contralateral kidney and bladder activity. **(b)** Left severe VUR in a 6-month-old infant with previously ablated PUV: Normal light kidney. **(c)** Poor-functioning left kidney at dimercaptosuccinic acid (DMSA) scan. (**[a]** From Glick PL et al., Management of the fetus with congenital hydronephrosis II: Prognostic criteria and selection for treatment, *J Pediatr Surg* 1985;20:376–387.)

These secondary consequences on the pathophysiology of the kidneys and lower urinary tract in boys with previous valves have a significant role in the management of these patients after obstruction removal.[38]

Pulmonary hypoplasia

During the pregnancy, oligohydramnios secondary to decreased fetal urine output produces an abnormally small uterine cavity. This compresses the fetus and interferes with the normal growth and expansion of the fetal thorax, resulting in pulmonary hypoplasia. The kidneys themselves have an important role in early lung growth, while the presence of amniotic fluid contributes to growth later in gestation. Amniotic fluid index (AFI) is an important marker of renal physiology during pregnancy. If severe oligohydramnios is present in early fetal life (19th–26th week gestational age), repeated maternal amnioinfusions or fetal bladder shunting may be considered, in the attempt to prevent lung maldevelopment. Preliminary hypoplasia represents the main cause of postnatal death in newborns with severe PUV or other congenital obstruction of the urethra.[39,40]

CLINICAL FEATURES

In the last three decades, advances in antenatal diagnosis have resulted in an increase in the number of babies with urinary tract obstruction being diagnosed either in utero or within the first few days of life, some of whom have posterior urethral obstruction. The ultrasonographic features of bilateral hydronephrosis in a male newborn with dilated and winding ureters, associated with an enlarged and poor-emptying bladder with thickened walls, are very suspicious for PUV or urethral diaphragm (Figure 106.5).

In the neonatal period, the baby may present with urinary tract infection, septicemia, uremia, and metabolic acidosis. Urinary symptoms may include a poor urinary stream, which can be an unreliable sign as some infants with severe obstruction have developed detrusor hypertrophy, enabling them to have a good stream. Quite often, the bladder and/or kidneys are palpable in infants with bladder outlet obstruction.[17,31]

More commonly, infants with PUV can present with chronic urinary stasis and upper tract changes, vomiting, failure, to thrive and loss of weight. Rarely, they may present with abdominal distension due to urinary ascites or perirenal urine collection. Urinary ascites is usually a result of perforation of the kidney, and in many instances, the site of the actual leak is not obvious radiologically. The newborn may present with a severe abdominal distension due to urinary tract dilatation and/or urinary ascites (Figure 106.6). Dispnoic or polypnoic breathing is often observed, as consequence of pulmonary dysplasia, metabolic acidosis, and abdominal distension.

INVESTIGATIONS

Ultrasound scan is the first diagnostic step that often is suggested by the prenatal sonographic studies during pregnancy. The ultrasound should be performed at earliest convenience. The kidneys are scanned to determine the severity of hydronephrosis and to identify any perineal collections of urine. The dilated ureters can be traced down to the bladder. In an uncatheterized patient, a dilated posterior urethra can be demonstrated by a perineal sagittal scan.

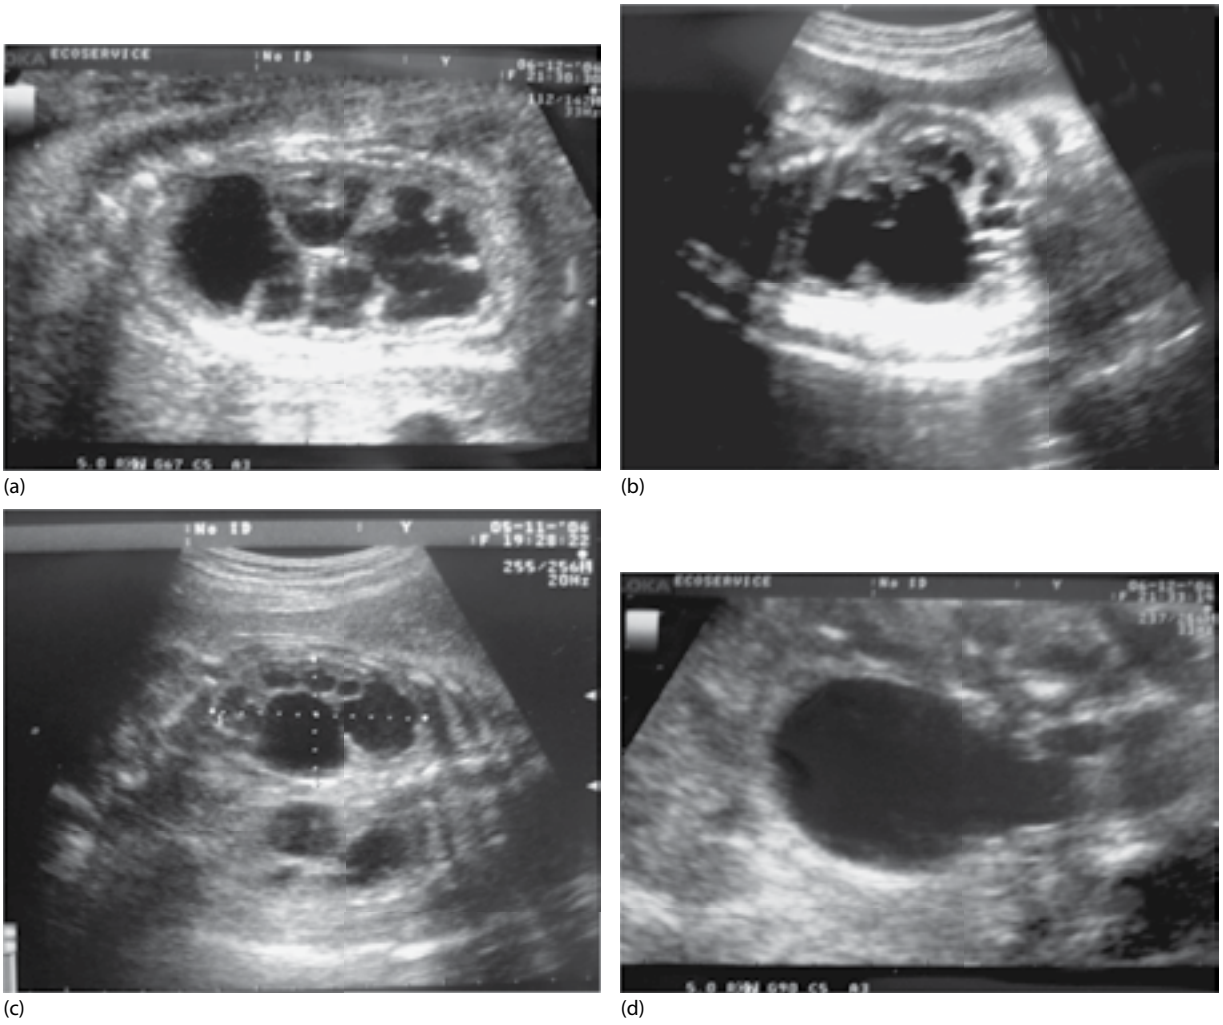

Figure 106.5 Prenatal ultrasonographic pictures of fetal urethra obstruction. **(a, b, c)** Bilateral hydronephrosis in a male newborn, with dilated ureters. **(d)** Enlarged and poorly emptying bladder, presenting thickened walls and wide bladder neck.

Figure 106.6 Picture of a very sick newborn with severe abdominal distension due to urinary ascites from congenital posterior urethral obstruction.

The bladder is thick-walled and with irregular edges, by the presence of pseudodiverticula (Figure 106.7).

After birth, once the infection has been brought under control, the diagnosis can be confirmed by a *micturating cystogram* (VCUG), which is the gold standard for the diagnosis of posterior urethral obstruction. The examination should be performed to record the micturition in the lateral oblique position. The following features can usually be demonstrated (Figure 106.8): trabeculated bladder walls, poor emptying, and dilatation and elongation of the posterior urethra, with prominence of the bladder neck, particularly the posterior lip. VUR may be present in many infants (Figures 106.3 and 106.4).

Intravenous pyelogram is nowadays not anymore utilized in infants and young children, as it has been replaced by ultrasound and radionuclide studies. Useful anatomical information on ureters for boys requiring upper tract surgery or bladder enlargement can be obtained by *magnetic resonance imaging* (MRI) studies (Figure 106.2).

Radionuclide studies should not be utilized in the neonatal period, but they are very useful to assess the later functional

status of both kidneys and to guide the urologist's decision on upper tract repair and on nephrectomy (VURD syndrome). In infants in whom a postoperative ultrasound scan shows no improvement, a mercaptoacetyltriglycine (MAG3) scan may help to distinguish between persistent obstruction and cystic dysplasia. The uptake is negligible in dysplasia. A renogram should be performed to assess the differential glomerular filtration rate, and the ureterovesical or pyeloureteral junction obstruction.

Urodynamic investigations are not usually performed at neonatal age or before valve ablation, but it is essential for the outcome evaluation of bladder changes across time.[41] Urodynamic studies are necessary to investigate the functional manifestation of the valve bladder syndrome and their relationship with urinary incontinence, voiding dysfunction and upper tract persisting dilatation. From initial patterns of hypercontractility in infancy and early childhood, bladder activity may gradually change to hypocontractility in many boys, especially after puberty[41] (Figure 106.9). The overdistended bladders in adolescence may lead to decompensation and increasing postmicturition

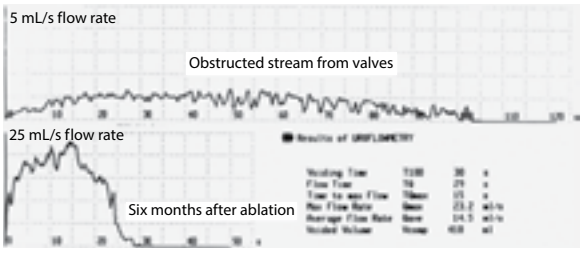

Figure 106.9 Uroflowmetry in a 4-year-old child with PUV. Reduced flow rate at presentation and normal pattern at 6 months after ablation.

residual and maximum bladder capacity. Upper tract persisting dilatation is a possible severe consequence, necessitating drug manipulation and/or intermittent catheterization.[36]

PRENATAL DIAGNOSIS AND MANAGEMENT

Urethral obstruction can be suspected in a male fetus with the introduction of screening ultrasonography and improvement of technology. A more frequent in utero diagnosis of PUV is now feasible.[42] Classic sonographic findings of PUV include a combination of megacystis, thickened bladder wall, dilated posterior urethra, with the "keyhole sign," and bilateral hydronephrosis in a male fetus (Figure 106.10). Oligohydramnios may be associated in more severe forms.[39] Even in the absence of these signs, antenatal diagnosis of urethral obstruction can be considered, especially in the presence of a constellation of findings including oligohydramnios and evidence of spontaneous urinary tract decompression (ascites, perirenal urinoma) (Figure 106.11).

Urethral obstruction in utero produces a wide variety of clinically significant effects in addition to obvious obstructive uropathy. Fetal urine is produced by the 13th gestational week, a decrease in the production of which results in an abnormally small uterine cavity. This compresses the fetus and interferes with normal growth and expansion of the fetal thorax, resulting in pulmonary hypoplasia. Bladder distension and urinary ascites expand the fetal abdomen and compromise the development of abdominal wall muscle, resulting in the prune belly appearance. In conclusion, prenatal ultrasound can accurately detect fetal lower urinary tract obstruction, with a sensitivity of 95% and a specificity of 80%.[43]

MRI may be increasingly used in the diagnosis and assessment of fetuses with lower urinary tract obstruction, enhancing the ultrasound findings.

Pulmonary and renal consequences vary in severity with the degree of urethral obstruction in utero, where high-grade oligohydramnios and pulmonary hypoplasia develop and lead to postnatal respiratory insufficiency and death. In less severe cases, enough urine passes to give a sufficient amniotic fluid volume to allow adequate pulmonary growth.

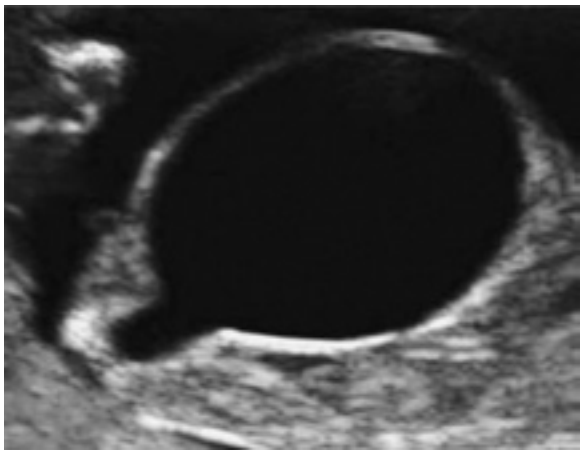

Figure 106.10 The "keyhole sign" of the fetal bladder at prenatal ultrasonography: Poorly emptying megacystis, with thickened bladder wall and dilated posterior urethra in a male fetus.

The advantage of prenatal diagnosis is considerable. The maternal and fetal management can be planned early, which usually results in maternal transport to a tertiary center where the newborn can receive optimal treatment immediately after birth. A flowchart on the prenatal management of PUV is presented in Figure 106.12.

Fetal lower urinary tract obstruction is a condition of high mortality and morbidity, associated with progressive renal dysfunction, oligohydramnios, and secondary pulmonary hypoplasia. *Intrauterine intervention* was developed from the pioneering research of Harrison and coworkers.[37,38] The most difficult problem has been the *selection* of the fetus with obstructive uropathy who might benefit from in utero treatment. Studies of the natural history of untreated congenital hydronephrosis have shown that the fetus with mild bilateral hydronephrosis and normal amniotic fluid volume requires no in utero intervention. Also, the fetus who presents with severe oligohydramnios and severely dysplastic kidneys sonographically is unlikely to benefit from antenatal intervention. Between the two groups, cases with obstructive uropathy can be observed, where potentially fatal renal and pulmonary damage may be averted by intervention. Prognostic criteria have been developed by Glick et al. (Table 106.1).[44] Fetal urine analysis may provide improvement in prenatal determination of renal prognosis. Anyway, precise criteria to guide prenatal management remain uncertain.[45] Further predictors of renal dysplasia have been examined in fetal obstructive uropathy, such as bladder pressure and beta-2-microglobulin assessment, to achieve prenatal evaluation of fetal renal function.[45]

It is possible to decompress the obstruction in utero, through *percutaneous vesicoamniotic shunting or cystoscopic techniques*. Quintero and colleagues[46] pointed to the technique and results of the insertion of a vesicoamniotic shunt passed either percutaneously using ultrasound or via a fetoscope, allowing the bladder to decompress into the amniotic cavity. The shunts are not satisfactory for long-term fetal urinary tract decompression due to the high incidence of catheter obstruction, displacement, and risk of chorioamnionitis.[47]

In appropriately selected fetuses, prenatal intervention may improve perinatal survival, but long-term renal damage remains mostly unsolved. Randomized multicentric studies are warranted.[48] At the moment, the initial enthusiasm has been reduced by the poor ability to modify the long-term outcome for the severely affected newborns. Open decompression for fetal obstructive uropathy is still in the experimental stage, awaiting further control trials to establish its efficacy.[47,48]

POSTNATAL MANAGEMENT OF NEONATES WITH POSTERIOR URETHRAL VALVES

Infants born with posterior urethral obstruction often may have often upper tract dilatation and renal damage

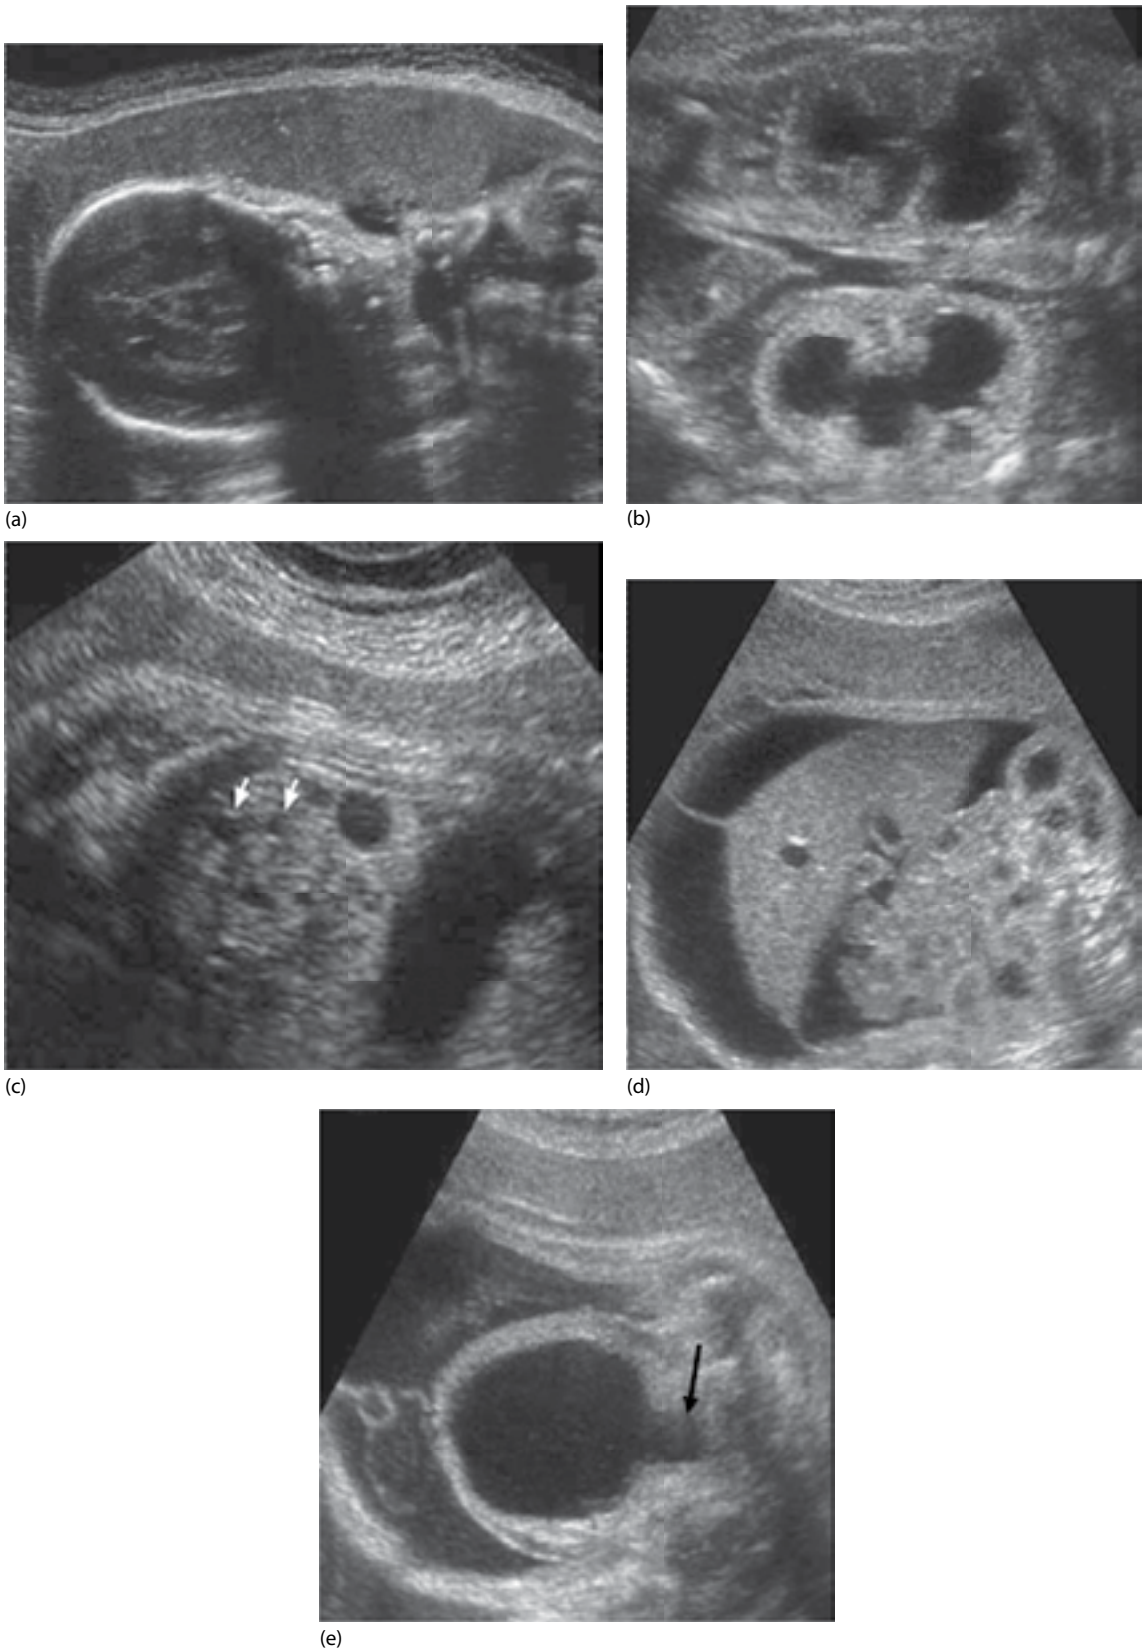

Figure 106.11 Prenatal ultrasonographic pictures. **(a)** Severe oligohydramnios. **(b)** Bilateral hydronephrosis. **(c)** Dysplastic kidneys. **(d** and **e)** Fetal urinary ascites with enlarged thickened bladder. The arrows indicate the exact point of the urine outflow obstruction caused by valves.

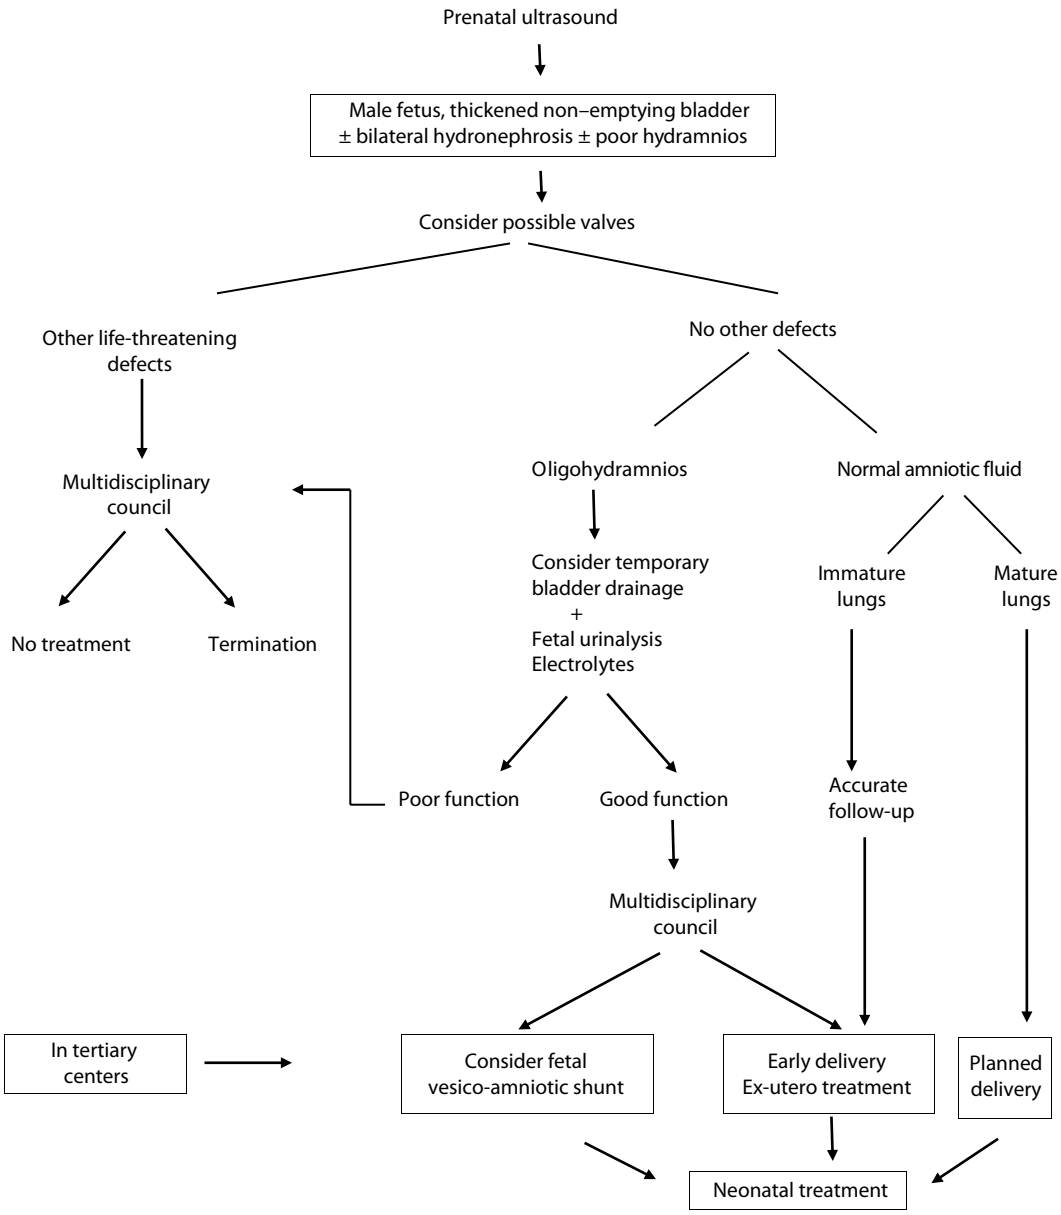

Figure 106.12 Posterior urethral valves: prenatal diagnosis and management.

Diuresis	=	>2 mL/h

that varies with the severity and duration of obstruction in utero. Most neonates with PUV when first seen are acutely ill with electrolyte abnormalities, metabolic acidosis, renal insufficiency, and septicemia (Figure 106.6). They may have respiratory distress, the severity of which will depend on the degree of associated pulmonary hypoplasia. Improved management of these neonates has resulted in a better outcome for the treatment of posterior urethral obstruction in the last two decades.

The *treatment strategy* in neonates with PUV can be divided into three stages:

1. Immediate management and confirmation of diagnosis
2. Surgical treatment of the obstructing valves
3. Long-term follow-up and treatment of associated pathology and complications

Immediate management

The initial resuscitation of the sick neonate and confirmation of clinical impression by ultrasound and VCUG is mandatory. Almost all neonates presenting with posterior urethral obstruction will need intravenous rehydration and electrolyte replacement. At the same time, blood samples can be obtained for the following:

- Full blood count, including platelet count, which may be low or high in septicemic babies.
- Urea, creatinine, and electrolytes, which should be estimated as baseline values.
- Blood and urine should be sent for culture and sensitivity tests prior to starting antibiotic therapy.
- Arterial blood samples to determine the degree of acidosis, to be treated by sodium bicarbonate infusion.

Temporary vesical drainage can be achieved by passing a fine feeding tube (size 5 or 6 Fr gauge) transurethrally. Balloon catheters are not suitable for vesical drainage in posterior urethral obstruction. Recently, the use of double-J transurethral stenting has been advanced.[49] If the bladder is not emptying, a suprapubic catheter can decompress the urinary tract without interfering with the congenital urethra obstruction and its radiological study. A sample of urine obtained on catheterization should be sent for microscopy and culture.

Once urine and blood samples are obtained for culture and sensitivity tests, the baby should be treated by antibiotic therapy. An aminoglycoside or cephalosporin is suitable initially, and changes can be made once the urine and blood culture results are available. Respiratory insufficiency should be considered and treated aggressively as and when necessary, and information of the respiratory states is given by means of a chest x-ray and blood gas estimation. A multidisciplinary team in the neonatal intensive care unit is often needed.

The confirmation of diagnosis usually involves a VCUG, performed when the general condition of the patient is improved and the infection is brought under control (Figure 106.8). However, an ultrasound scan can be done even in a sick neonate, by a sagittal perineal scan. The keyhole sign, although specific, cannot always be observed.[50]

Surgical treatment of congenital PUVs

Release of the congenital obstruction in a male newborn with PUV should be considered as early as possible, because the indwelling transurethral catheter is only very transient, for the risk of serious urinary tract infections and of defunctionalized bladder retraction. There is no consensus as regards the optimum method of treatment of posterior urethral obstruction, and its management constitutes an ongoing challenge in pediatric urology practice. The range of opinion varies from primary ablation alone to upper renal tract drainage, followed by delayed ablation. Ideally, the treatment option should be individualized, depending on the condition of the baby, the state of the upper renal tracts, and the size of the baby's genitalia.

PRIMARY TRANSURETHRAL RETROGRADE ABLATION

It can be performed under endoscopic view or blindly, depending on the preference of the surgeons and the available instrumentation.

Retrograde endoscopic ablation

It is the treatment most widely utilized, thanks to appropriate neonatal cystoscopes and resectoscopes now available, which may reduce the risk of secondary urethral damage and strictures in the newborn.[51] Fulguration can be undertaken once the infant's overall condition and renal function have stabilized. The development of smaller endoscopic equipment, as well as improved fiber optics, has permitted transurethral endoscopic incision or fulguration of posterior urethral obstruction in virtually all but the most premature patients. In most cases, primary ablation is sufficient to decompress the bladder and upper renal tracts.

Bugbee electrodes, available for use with the 8 Fr cystoscope, can be used for fulguration of PUV. One satisfactory alternative is to use a 3 Fr ureteric catheter with a metal stylet that can be used to coagulate. This can be passed through the side channel of an 8 Fr cystoscope. The obstructing membranes are incised at the 5, 7, and 12 o'clock positions. The neonatal resectoscope is commonly used in term newborns, as the caliber is 8 Fr (Figure 106.13). This instrument allows hooking of the valve leaflets and cutting them with more precision than the Bugbee catheter. It must be stressed that the valves or the congenital obstructive membrane should not be resected, but a full section of the leaflets should be undertaken at 5, 7, and 12 hours (Figure 106.14). The section is enough to release the bladder outlet obstruction and avoid the main severe complication that is postoperative urethral stricture. The reported incidence of strictures following endoscopic ablation is between 3.6% and 25%, but incidence of 0% has been reported with improved delicate maneuvers.[51]

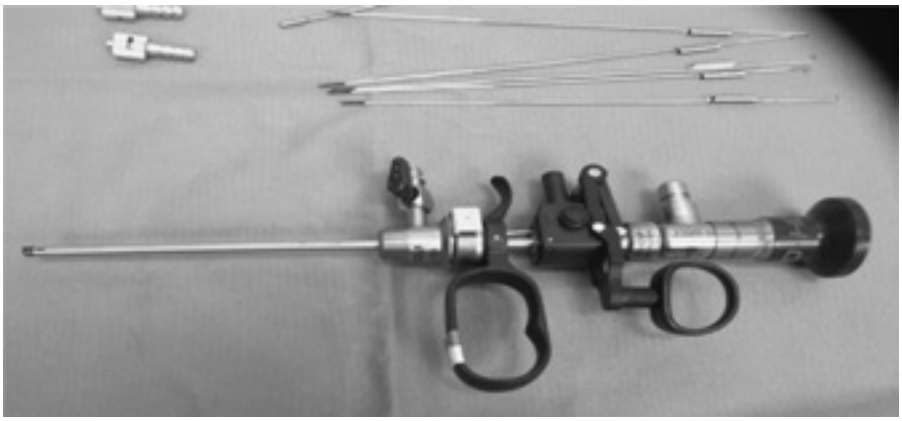

Figure 106.13 Neonatal resectoscope, suitable in newborns presenting congenital obstructing membrane or valves on posterior urethra.

Blind transurethral ablation

Especially in very small newborns or premature babies, transurethral endoscopy cannot be accomplished without the risk of urethral injury. Blind ablation of valves and urethral diaphragm was performed, utilizing different instrumentation and techniques.

1. *Fogarty balloon catheter*
   The baby is anesthetized, and a 6 Fr urethral catheter is passed transurethrally. The bladder is filled with contrast material until the posterior urethra is filled and an obstructing membrane identified. The catheter is then removed, and under fluoroscopic control, a no. 4 Fr Fogarty balloon catheter is placed into the bladder and inflated with approximately 0.75 mL of saline. With gentle withdrawal, the operator visualizes engagement at the level by the balloon. Sharp withdrawal of the catheter ruptures the valves or the membrane without injuring the sphincter.[52] Postoperative catheter drainage is recommended for 48–72 hours.
2. *Mohan's valvotome*
   This simple instrumentation may solve the problem of valve ablation in little infants. The advantages of the technique are its suitability in small neonates and the fact that it can be performed in areas of the world where pediatric endoscopic equipment is not easily available. However, a significant number of children have shown urethrorrhagia and periurethral extravasation of contrast in a postablation cystourethrogram.[53]
3. *Whitaker–Sherwood diathermy hook*
   Innes Williams successfully used a diathermy hook to ablate posterior urethral obstruction. Whitaker and Sherwood have modified the hook to its present form, which is fully insulated, except for the inside of the hook itself where the metal is bare for application of the diathermy.[54] The advantages are its small caliber, 6–7 Fr, and applicability without the need for a general anesthetic. However, the proximal end of external stricture is above the obstruction, putting the sphincter at risk.

   The sterile lubricated hook is passed up the urethra, pointing to the 12 o'clock position, with the bladder full of contrast medium. The obstructive membrane is immediately engaged by rotating it to either side, and often, it will not disengage until the diathermy is applied. The obstructing membrane is destroyed with the smallest effective diathermy current at the 3 and 9 o'clock positions, and elsewhere if it can be reengaged.

   With the advances in small cystoscopes, all these relatively blinded techniques are less favored in recent years.

Primary antegrade ablation

A *percutaneous antegrade ablation* technique was proposed by Zaontz,[55] combining the techniques of antegrade urethral obstruction ablation and percutaneous endoscopy. The disadvantages of urethral instrumentation are avoided, and the technique is applicable even in small premature infants.

Antegrade laser ablation has been proposed by some authors[56,57] in newborns. The Nd:YAG laser can be used via antegrade or retrograde access. The main advantage should be the limited inflammatory response of the injured tissue, with reduced risk of bleeding and of secondary stenosis.

Initial urinary diversion followed by secondary transurethral ablation

There is general agreement on some indications for temporary diversion in neonates, including prematurity, small body size, and/or small urethral caliber with massive VUR.

VESICOSTOMY

In 1974, Duckett[58] described the use of cutaneous vesicostomy as an alternative to primary ablation in a neonate. By creating a vesicostomy, urethral instrumentation is avoided, high voiding pressures causing persistent high-grade reflux are managed, and hydroureteronephrosis due to poor ureterovesical drainage is relieved. The bladder should be closed at the time of the subsequent diathermy of the urethral obstruction. However, vesicoureteric junction obstruction

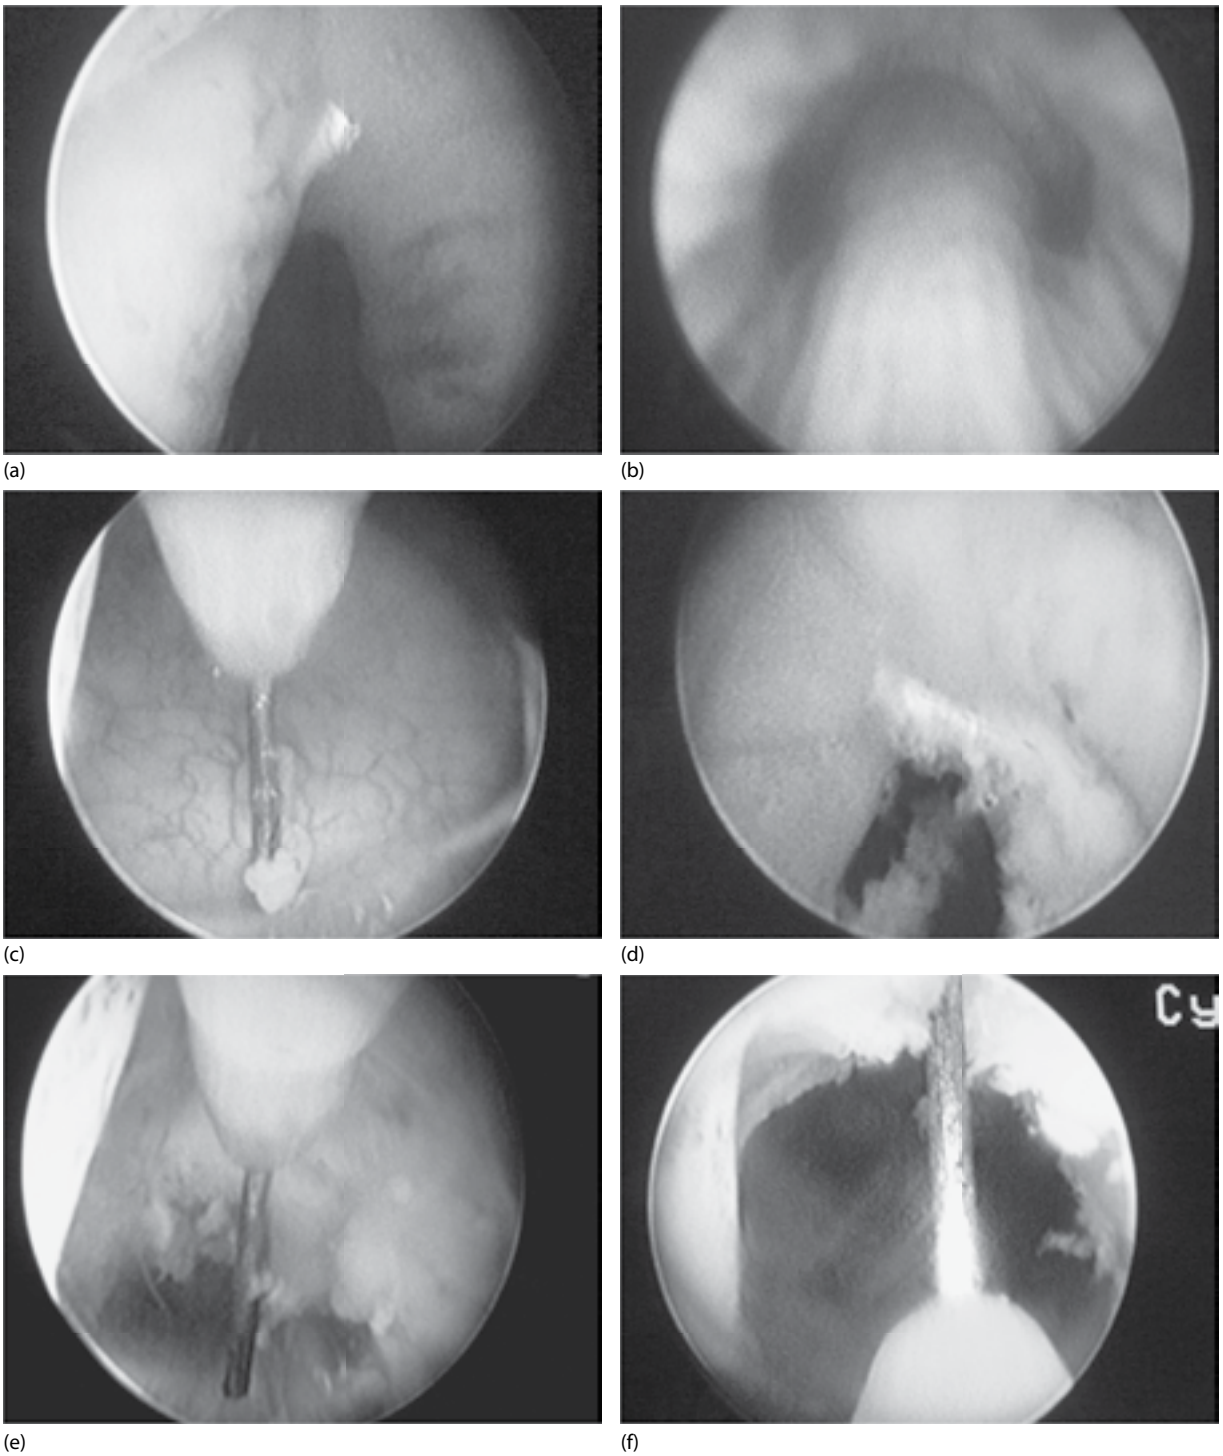

Figure 106.14 Endoscopic pictures of the section of the valve leaflets; a male newborn with PUV. **(a)** The obstructing membrane. **(b)** Dilated prostatic urethra. **(c)** Diathermic hook. **(d** and **e)** The valve flaps are hooked at 12, 5, and 7 hours. **(f)** Final appearance after PUV fulguration.

and shrinkage of a defunctionalized hypertrophied bladder may occur, if the vesicostomy is long-term.

UPPER TRACT DIVERSION

Upper tract diversion in posterior urethral obstruction is practiced in some limited indications. Primary ablation or temporary vesicostomy will be enough for hydroureteronephrosis to resolve in most cases. But for severe or late-presentation cases, and if significant dilatation of the upper tract persists, in spite of lower tract drainage and ablation, nonintubated upper tract drainage may be beneficial. However, we know that dilatation does not mean obstruction and that

temporary nephrostomy diversion in the use of double-J catheters may ameliorate the hydronephrosis. In a series by Krueger and associates[59] infants treated with high-loop cutaneous ureterostomy ultimately had better outcome with regard to renal function and growth than the group managed by primary transurethral ablation of the valves. Reinberg et al.[2] demonstrated in 79% of patients who were treated initially with high diversion that mild to severe renal failure developed, versus 47% with primary ablation. Although no controlled study has been conducted, unilateral low ureterocutaneostomy could be useful in the case of VURD syndrome with refluxing ureter and nonfunctioning kidney, allowing urinary tract decompression without interfering with bladder cycling and maturation in the small infant.

TEMPORARY NEPHROSTOMY DIVERSION ON INSERTION OF DOUBLE-J STENTS

If the upper tract is needed in spite of a successful ablation, temporary nephrostomy with an insertion of double-J stents may be useful in patients with vesicoureteric junction obstruction or severely dilated upper tract. The insertion of double-J stents prevents dry bladder and keeps the bladder cycle, which is needed for normal bladder development.

Early postoperative management

The urethral catheter is left in situ after valve ablation for 48–72 hours, to allow the edema to subside and the urinary output to be measured. Accurate hydroelectrolytic balance is monitored by intravenous fluids and electrolyte solutions. Serial serum creatinine, electrolytes, and urinalysis are monitored after the patient is discharged with antibiotic prophylaxis. Postvoid residual urine volume is frequently checked by ultrasound, and sonographic appearance of kidneys and the upper tract is observed at 4–6 months' interval time. If the postvoid residual urine volume is significant (greater than 10% of expected bladder capacity), alpha-1 adrenergic blocker drug treatment can be started (terazosin 0.04–0.4 mg/kg per day), after obtaining informed consent. Blood pressure must be monitored routinely.

The first VCUG is usually performed at 3 months from valve ablation, and a "second-look" cystoscopy is indicated if residual valves or leaflets are suspected, to guarantee full urethral disobstruction. A simple measurement that allows quantitative assessment of valve ablation is the *urethral ratio* on VCUG.[60] A postfulguration urethral ratio of 2.5–3.0 represents a positive result postoperatively. Renal radionuclide scan (MAG3 or DMSA) is suggested at 6–12 months from valve ablation to check parenchymal function.

FOLLOW-UP AND TREATMENT OF LONG-TERM SEQUELAE AND COMPLICATIONS

Urethral stricture

It can be a significant complication following the transurethral approach for treatment of PUV, as a consequence of mechanical trauma on the posterior urethral wall. The stricture can happen where the lesion on the urethral wall is deeper and the *corpus spongiosum* could be injured. The incidence of urethral strictures following PUV ablation has been reduced from 25% to near 0%, but it can be avoided, utilizing small endoscopes and delicate maneuvers.[51,61]

DYSFUNCTIONAL VOIDING AND URINARY INCONTINENCE

Valve bladder syndrome

Early valve ablation allows the bladder to fill and empty with normal cycling, starting shortly after birth. The restored bladder cycling is crucial for regaining its normal function and dynamics.[62] Mitchell suggested the term "valve bladder syndrome" to denote the association of a noncompliant bladder and upper tract dilatation in boys with a history of previous PUV.[30]

At least 30% of children with previous PUV have different degrees of dysfunctional bladder. It often presents with daytime and nighttime urinary incontinence at the toilet-trained age. Initially it was thought to be secondary to external sphincter incompetence, depending on primary maldevelopment of the sphincteric urethra, rather than iatrogenic injuring of this structure during endoscopic manipulations. Further urodynamic studies showed the presence of vesical dysfunction, which does not resolve after complete urethral obstruction removal.[41]

A number of different voiding dysfunction pictures may be present after primary valve ablation in children born with PUV. The incidence of voiding dysfunction in posterior urethral obstruction has been reported to occur in 13%–38% of all patients treated, of which incontinence is the most common problem.

The main bladder anomalies causing incontinence are *detrusor overactivity, reduced compliance, and myogenic failure*. Detrusor overactivity and reduced compliance are treatable with anticholinergic pharmacotherapy, but bladder augmentation may be necessary in selected cases. Myogenic failure may be most effectively treated with clean intermittent catheterization and nocturnal bladder emptying.[38]

The evolution over the years of this severe bladder dysfunction may lead to upper tract dilatation and renal function deterioration.[29,30,38] Serial urodynamic studies, with pressure-flow analysis and evaluation of postvoiding urine residual, are necessary. Bladder activity may change over time from a hyperactive, low-compliant, and reduced-functional-volume bladder to hypocontractile, high capacity, and poor emptying behavior (decompensated bladder with myogenic failure).[41,63]

Early valve ablation, even in patients with severe bladder changes, could provide better bladder function results, with higher resolution rate of VUR and hydronephrosis. Bladder neck incision, performed simultaneously to valvulotomy or later in infancy or childhood, has been advocated to increase low-pressure bladder outlet if pharmacological treatment by alpha-1 adrenergic blockers drugs were not efficacious.[64]

VUR and hydronephrosis

The incidence of VUR in boys with PUV is high, bilateral in 37% and unilateral in 27% of patients.[65] Children born with bilateral high-grade VUR are at greater risk for CRF than those with unilateral or no VUR. Unilateral VUR may confer a protective pop-off effect in the contralateral kidney.[35]

A high rate of reflux resolution is expected after valve ablation, even in presence of vesical diverticuli, with a consistent follow-up. VUR resolution is correlated with bladder dysfunction normalization. In a recent series of Heikkila and coauthors,[65] VUR resolved spontaneously in 62%, was corrected by antireflux surgery in 21%, and required nephrectomy in 17% of boys with previous PUV. Indications for ureteral reimplantation remain undefined today, but the recent experience tends to support a less aggressive surgical approach than in the past.

Pyeloureteral dilatation persisting after treatment of an obstructing membrane is due to either vesicoureteric junction obstruction or ureteral atony. Diuretic renograms may be helpful in the differentiation between the two conditions, although temporary drainage of the upper tract may be necessary to make the diagnosis. A conservative approach, with care to bladder dysfunction treatment, is often recommended today.

Renal dysplasia

Unilateral renal dysplasia with a nonfunctioning kidney should be treated by nephroureterectomy, if at risk for blood hypertension or urinary tract infections. Bilateral renal dysplasia will go on to develop into end-stage renal disease and will require dialysis and renal transplantation.

PROGNOSTIC FACTORS IN PUV

Congenital lower urinary tract obstruction is a disease of high mortality and morbidity in pediatric age. With the widespread use of prenatal ultrasound, most children with PUV are now recognized prenatally and confirmed at birth. Several prognostic factors have been underlined to better define the long-term outcome of a baby born with PUV.

- Prenatal prognostic factors for better postnatal outcome have been presented and discussed in the section "Prenatal Diagnosis and Management." Poor prognosis is related to reduced amniotic fluid volume, presence of cortical renal cysts, and other congenital or structural anomalies of the fetus.[45]
- Ultrasound findings of reduced parenchymal thinness, increased renal echogenicity, and cystic changes in neonatal age of infancy are usually correlated with severe renal damage and dysplasia, evolving into CRF.[43]
- Urinary extravasation with or without ascites in prenatal or neonatal age, large bladder diverticula, and VURD syndrome are all factors decompressing the urinary tract and related to a better renal function outcome.[34,35]
- Delayed presentation of patients with PUV (after 2 years of life) are at higher risk of developing CRF on long-term follow-up.[66] Early vesicostomy or other urinary diversion is not confirmed to give better outcome.[67]
- Early primary valve ablation of PUV seems to lead to better outcome than urinary diversion, reducing bladder dysfunction.[62]
- Unilateral gross VUR, associated with poor-functioning ipsilateral kidney, may give a protective effect in the contralateral kidney (pop-off valve syndrome).[35]
- Bilateral high-grade VUR is at greater risk for renal insufficiency, although not always confirmed.[65]
- Severe bladder dysfunction (valve bladder syndrome) may jeopardize the upper tract and renal function at long-term follow-up.[38,41]
- Proteinuria, blood arterial hypertension, and febrile urinary tract infections do not correlate significantly with the ultimate functional outcome.[68] The nadir creatinine values of 0.8 mg/dL or higher within the first year of life are reported as the most significant prognostic factor correlated with poor renal function in the long term.[69]
- Renal transplantation can be offered to children with a history of previous PUV or congenital obstruction of the posterior urethra, with the same good results as other pediatric candidates, with preemptive urological repair of the lower urinary tract.[70]

CONCLUSIONS

Congenital obstruction of the male posterior urethra represents a spectrum of lesions, of which PUVs are the most common picture. It often remains a severe structural cause of a urinary outflow obstacle in newborn age and in infancy. It still represents one of the most significant causes of end-stage renal failure before the age of 2 years.[3,68] Prognosis of children born with PUV has improved significantly over the past two decades, but till now, a high number of patients enter CRF and progress to end-stage renal insufficiency by adolescence, with the need for a dialysis–renal transplant program.[69] A precise multidisciplinary approach may further improve the outcome of these children, providing a more pathogenetic and appropriate treatment at long-term follow-up, till adulthood.

Neurogenic bladder in the neonate

SALVATORE CASCIO AND MALCOLM A. LEWIS

INTRODUCTION

Neurogenic bladder in the neonate can be divided into three groups—primary, secondary, and idiopathic. *Primary neurogenic* bladder develops as a result of a lesion at any level in the central nervous system, cerebral cortex, and spinal cord, or in the peripheral nervous system. The most common causes are open or closed congenital neural tube defects (spinal dysraphism). Other forms of neurological injury (e.g., cerebral palsy) can be associated with neurogenic bladder. Outside of the spinal cord, primary neurogenic bladder can result from lesions such as sacrococcygeal teratomas. *Secondary neurogenic bladder*, also called neuropathic bladder, occurs when the bladder acts like a neurogenic bladder but is not caused by a neurological defect. Causes in a neonate include imperforate anus, prune belly syndrome, bladder exstrophy, cloacal exstrophy, and posterior urethral valves. *Idiopathic neurogenic bladder* is very rare; causes include the urofacial syndrome. Where this is not present, idiopathic neurogenic bladder is a diagnosis of exclusion once primary and secondary causes have been excluded.

The incidence of neural tube defects in Europe is heterogeneous with some regional registries showing a higher rate than others, with an overall rate across Europe of 0.49 per 1000 live births.[1] In the United States, the incidence of spina bifida has recently plateaued at approximately 0.3 per 1000 live births.[2]

The optimal management of a neurogenic bladder in the neonatal period is controversial, with no agreement among pediatric urologists and nephrologists on when clean intermittent catheterization (CIC) and anticholinergics medication should be commenced, and no consensus on the timing of renal investigations (micturating cystogram and dimercaptosuccinic acid [DMSA]), videourodynamic studies, and urological follow-up. However, general agreement exists that the key element in the urological management of these patients remains the early recognition of those bladders at risk for upper and lower urinary tract deterioration in order to start adequate medical or surgical treatment, thereby preventing renal and bladder damage and improving long-term outcome.

PRENATAL DIAGNOSIS AND COUNSELING

It is unusual to make a diagnosis of neurogenic bladder antenatally on the basis of the ultrasound (US) appearances of the renal tract. For the vast majority of patients, the diagnosis of neurogenic bladder is assumed following the finding of evidence of spinal dysraphism, open or closed, on antenatal scan. In patients with spinal dysraphism, it is virtually unknown for neurogenic bladder to present as antenatal hydronephrosis or an enlarged bladder in the absence of other congenital anomalies affecting the renal tract. The only situation where primary neurogenic bladder will present as antenatal hydronephrosis is where the child has urofacial (Ochoa) syndrome.

In cases where primary neurogenic bladder is suspected because of spinal dysraphism, it is appropriate for the urologist or nephrologist to be involved early in the counseling process. Families need to know that in cases of open spinal dysraphism, the incidence of neurogenic bladder is over 90% and what the implications of this are for the child in terms of continence, dependence, and the risk of developing renal functional impairment. The latter can occur even with optimal management of the neurogenic bladder, and it needs to be noted that, with high open spinal dysraphism lesions, accompanying renal dysplasia with the potential for renal functional impairment is more common.[3] Where a closed spinal dysraphism lesion has been detected, figures from our series of over 300 patients in Manchester, United Kingdom, show that the risk of neurogenic bladder varies from 28% in patients with isolated lesions, such as a long cord, diastem, or pure meningocele, to 66% in those with lipomyelomeningocele, to over 90% in those with sacral agenesis/dysgenesis.

The counseling process needs to provide the family with a clear outline of the problems facing the child after birth, the management options available, and the prognosis. Depending on the overall prognosis for the child, taking into account the neurological outcome based on the lesion, the availability of potential interventions and the legal requirements of the locality of the family, there are four options available. The *first* option is termination

of the pregnancy. This is a common choice in some countries like the United Kingdom but rare in others. This is influenced not only by the legal framework of the locality of the family but also by their religious and ethical beliefs and those of their community. The *second* option, in cases of open spinal dysraphism, is antenatal surgical repair. This is only available in a small number of centers. As an intervention, the benefit of antenatal repair has not yet been proven. The spinal dysraphism still exists, and the antenatal surgery effectively changes an open lesion into a closed lesion. This certainly reduces the incidence of hydrocephalus and ventriculoperitoneal shunt placement with improved mental development and motor function measures at age 30 months following in utero closure.[4] However, it is unclear if prenatal closure will significantly improve bladder outcomes.[5] The process itself is far from complication-free. Preterm delivery, with secondary complications, is frequent. The *third* option is progression to term and active management of the infant after delivery. The *fourth* option, only available in cases where the combined anomalies clearly confer a very poor prognosis for the child, and where nonintervention will lead to fairly rapid death, is palliative care for the infant.

The final decision about a course of action in an individual case is dependent upon the decision of the family, influenced heavily by the legal framework of the locality and resources available. There are no "right" answers, and families have to decide which option is best for them based on the clinical information imparted to them and their own beliefs and circumstances.

In cases of neurogenic bladder secondary to other congenital anomalies of the renal tract or associated disorders, the information imparted to the family will be strongly influenced by the underlying condition. The management options will also be determined by this. The antenatal options are effectively the same as the aforementioned, though antenatal surgery is not usually an option, and antenatal drainage of a distended bladder remains an option of unproven benefit.

ANATOMY AND MICTURATION PHYSIOLOGY

The autonomic and somatic nervous systems are involved in the innervations of the bladder and sphincter; the parasympathetic component of the autonomic innervations is derived from the sacral segments of the spinal cord. These fibers emerge as preganglionic fibers within the pelvic nerve, which then joins the hypogastric nerve to form the bladders plexus. The postganglionic fibers emerge from synapses close to the bladder and urethra, where they have the overall effect of producing sustained bladder contraction. Acetylcholine is the neurotransmitter for both the preganglionic and postganglionic fibers, although there is certainly more than one principal neurotransmitter. Within the bladder, the parasympathetic cholinergic receptors are largely muscarinic (M2). Other neurotransmitters documented to be present in the bladder include the following: vasoactive intestinal peptide, neuropeptide Y, substance P, somatostatin, calcitonin gene-related peptide, cholecystokinin, dopamine, serotonin, histamine, and tyrosine hydroxylase. The exact roles of these neurotransmitters, as well as their complex interactions, remain unclear.

The sympathetic component of the autonomic innervations arises from spinal cord segments T11–L2, with preganglionic fibers traveling to the hypogastric and inferior mesenteric ganglia, where they synapse with the noradrenergic, postganglionic fibers, which in turn travel to the bladder and urethra via the hypogastric nerve. Sympathetic input is mediated by both α and β adrenoreceptors. The α adrenoreceptors are more densely represented at the bladder base and produce contraction, while the β adrenoreceptors, which are more common in the bladder body, produce relaxation. Thus α activity promotes outlet resistance, while β activity promotes urine storage and opposes cholinergic tone.

Somatic motor innervations arise from the S2–S4 segments and pass via the pudendal nerve to the striated muscle of the external sphincter. While the external sphincter is a voluntary muscle, in infancy, external sphincter tone is mediated via spinal cord reflex. It is only as the child matures that cortical inhibitory influences develop that allow voluntary relaxation and contraction, which contribute to the development of continence.

Normal bladder sensation is relayed via pelvic and hypogastric nerves, with parasympathetic visceral afferent fibers transmitting information from pain, temperature, and stretch receptors.

In the newborn and infant, voiding occurs as a result of a spinal reflex secondary to bladder distention, which stimulates the efferent limb of the reflex arc, resulting in spontaneous detrusor contraction. Initially, as the bladder fills, the periurethral striated muscles make the external urinary sphincter contract to prevent urine loss. The act of micturition occurs with subsequent relaxation of the external sphincter, resulting in the bladder emptying at low pressure. During the first year of life, the number of voiding episodes per day remains constant at about 20, occurring both during sleep and while awake; with increased age, there is a reduction in the voiding frequency that relates to the relative increase in bladder volume and decreasing proportion of the caloric intake associated with fluid.

CLASSIFICATION

There are many classifications describing neurogenic bladder dysfunction. Most of these classifications are dependent on the site of the neurological lesions, well adapted to adult pathology but not to congenital spinal lesions. In fact, in children, there is poor correlation between the spinal level of the lesion and the clinical impact. For this reason, classification based on clinical appearance and urodynamic findings is more practical in children. The two elements determining the clinical appearance are the state of the bladder muscle and the state of the sphincter. The bladder muscle can be

contractile (63%), acontractile with good compliance (20%), or acontractile with poor compliance (17%). In each of these states, the sphincter can be completely denervated (36%), partially denervated (24%), or with an intact sacral reflex arc (40%)[6] (Figure 107.1). It is the state of the sphincter that is the primary determinant of both continence and the potential for upper tract damage. A lax sphincter will be associated with urinary incontinence but safe upper tracts. A tight sphincter will be associated with urinary retention. With a tight sphincter and an acontractile bladder, there is the easy potential for continence using CIC. Where the sphincter is tight but the bladder is poorly compliant, the bladder pressures will be high, leading to obstructive uropathy. An overactive bladder will potentially both lead to urinary leakage and place the upper tracts at risk depending on how tight the sphincter is and at what pressure leakage occurs. This is where dyssynergia becomes important. If, as is commonly the case in infants with open spinal dysraphism, there is detrusor sphincter dyssynergia (DSD), then, even if the resting state of the sphincter tinge is low and leakage is readily occurring, there is a risk to the upper tracts because sphincteric spasm at the time of detrusor contractions can cause pressures high enough to lead to obstructive uropathy. Determination of how the bladder is functioning is achieved with urodynamics. However, it needs to be appreciated that urodynamics just give a snapshot of bladder function at one moment in time. The pattern of activity seen during urodynamic testing may not be replicated throughout the day, every day. Moreover, the neurogenic bladder is not static and changes with time. Thus, urodynamic assessment cannot be used to manage the patient independently. It has to be used in combination with other investigations and full clinical assessment.

Videourodynamics

The basis for major clinical decisions in patients with neurogenic bladder rests mainly on assessment of the upper tracts with US scan and assessment of the bladder with urodynamics. It needs to be remembered that the aim in infants is to ensure the safety of the upper tracts, not provide continence. Particularly in infants, performing videourodynamics, rather than urodynamics alone, allows both functional and concurrent visual assessment of the

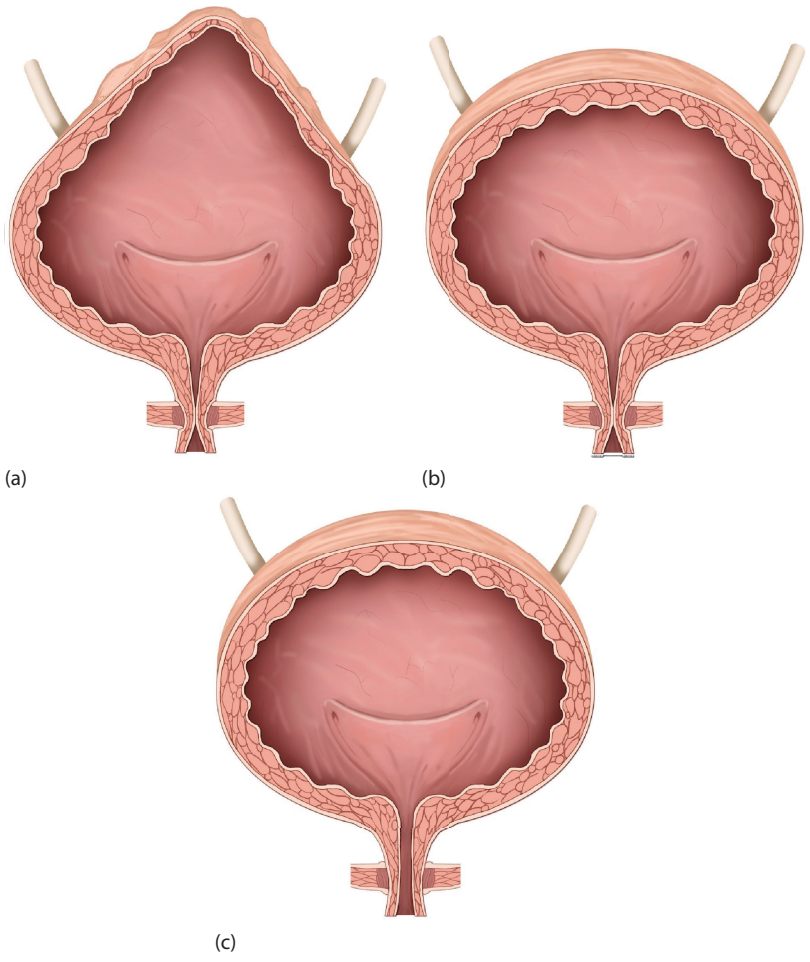

Figure 107.1 Videourodynamic findings in newborns with myelodysplasia. **(a)** Dyssynergy (37%). **(b)** Synergy (26%). **(c)** Complete denervation (36%). (From Bauer SB, Initial Management of Meningocele Children, in *Textbook of Neurogenic Bladder*, 3rd ed, pp. 633–644, Jacques Corcos, David Ginsberg, Gilles Karsenty, eds, CRC Press, Taylor & Francis Group, 2015.)

bladder, giving more information for decision making. The principles of urodynamic assessment in infants are the same as for older children and adults, but obtaining reliable and interpretable results is more difficult. Moreover, it has been well demonstrated that normal infants frequently show a picture of incomplete voiding and dyssynergic voiding on urodynamic testing.[7] Thus careful interpretation of the test, taken in conjunction with the clinical picture, the appearances on US scan, and the appearances on video images during urodynamics, is required when making decisions on urodynamic results. The mainstay of urodynamics is the measurement of detrusor pressure during a filling cycle, judging from this the bladder capacity at an acceptable pressure and the leak point pressure. The use of a rectal probe to measure abdominal pressure potentially allows the measurement of the true detrusor pressure, through subtraction of the abdominal pressure from the intravesical pressure. Sadly, getting a good rectal pressure trace can be difficult, and spontaneous rectal contractions or rectal contractions in combination with detrusor contractions are common and can give a false impression of what the true detrusor pressure is—often underestimating this. Thus, there is no substitute for carefully watching the intravesical pressure trace during a test and using this as the primary reference point. Similarly, the use of electromyography in the test will potentially give information about the background level of sphincteric activity and whether there is DSD. However, any movement makes this trace difficult to interpret, and the iron test of the risk of developing obstructive uropathy is the pressure at which leakage occurs and the intravesical volume associated with pressures over 30 cm of water. The information from concurrent videofluoroscopy is invaluable and gives a visual impression of the contour of the bladder and whether there is trabeculation of the bladder or diverticulae. The state of the bladder neck can be seen. Most importantly vesicoureteric reflux (VUR) can be identified. If VUR is present, measurements on fluoroscopy or US can be used to assess the true bladder capacity and hence compliance, which can be significantly less that the infused volume used in urodynamics with no fluoroscopy.

DIAGNOSIS AND ASSESSMENT OF NEUROGENIC BLADDER IN THE NEONATE

The initial assessment of a newborn with a neurogenic bladder begins in the first few days of life with a detailed physical examination, evaluating the presence of a palpable bladder or kidney, and a comprehensive neurological examination, looking for spontaneous movement, checking for muscle wasting and deep tendon reflexes, and testing sensation in the lower extremities and of the anus. The tone of the anal sphincter could be indicative of the type of lesion, as a patulous anus suggests a complete lower motor neuron lesion, while the presence of anal contraction to gentle scratching of the rugated perianal skin implies some intact sacral spinal cord function and reflexes.

Open neural tube defects are usually closed in the first 24–48 hours, and an indwelling Foley catheter is placed at the time of closure to ensure adequate bladder drainage and to reduce contamination of the healing wound. The catheter is left for 5–7 days, until the wound is healed and it is safe to nurse the patient on the back. Once the indwelling catheter is removed, it becomes essential to establish if the baby is able to empty the bladder. This can be achieved with a nappy alarm with assessment of voided volume (weighing the nappies) and measurement of postvoid residual with US. The constant leak of urine into the nappy with no postvoid residue would suggest a lax sphincter with a low leak point pressure, resulting in little risk to the upper tract. On the contrary, high residual (above 5 mL in the neonate) would imply a degree of sphincter spasm or dyssynergia with high leak point pressure and increased risk of upper tract deterioration. Spinal shock following myelomeningocele closure occurs in 3% of newborns, but it can last for 2–6 weeks after surgery; therefore, the initial bladder assessment might need to be repeated at the first follow-up appointment.[8] A renal and bladder US is a key element of the initial assessment. As mentioned previously, neurogenic bladder does not cause hydronephrosis and obstructive uropathy antenatally. At birth, the kidneys of neonates with neural tube defect are normal in the large majority of patients. In our database of 248 newborns with neural tube defect at the Children's University Hospital, Dublin, we have detected at birth 18 (7%) urological anomalies: 6 duplex kidney, 6 hydronephrosis, 4 horseshoe kidney, one pelvic kidney and one single kidney. Urological anomalies were found more commonly in the thoracolumbar and lumbosacral lesions with no correlation between the sensory level of the neural tube defect and the type of urological anomaly. Thus, where abnormalities are found, they are the result of concomitant renal tract anomalies or dysplasia.[3] A baseline DMSA renogram is organized after 3 months of age, while an early micturating cystourethrogram has been replaced in our institution by videourodynamics in the first 3–6 months of life (Figure 107.2).

For patients with closed lesions, there is not likely to be any early surgical intervention, so there is no need for an early indwelling catheter. Following initial clinical assessment, bladder assessment begins with the observation of the baby's voiding pattern and postmicturition volumes. These are then taken in conjunction with the renal US scan, DMSA scan, and later videourodynamics.

Management of neurogenic bladder

The initial management of a newborn with neurogenic bladder is centered on the preservation of renal function. Two different management options are available: the expectant and the proactive approach.

A relatively *expectant* approach is preferred for closed spinal defects, where the risks of neurogenic bladder are lower. In these patients, as long as initial assessment suggested they are voiding regularly, close follow-up is recommended with ultrasonography, urinary surveillance, and monitoring of bladder emptying every 3 months, together with selective

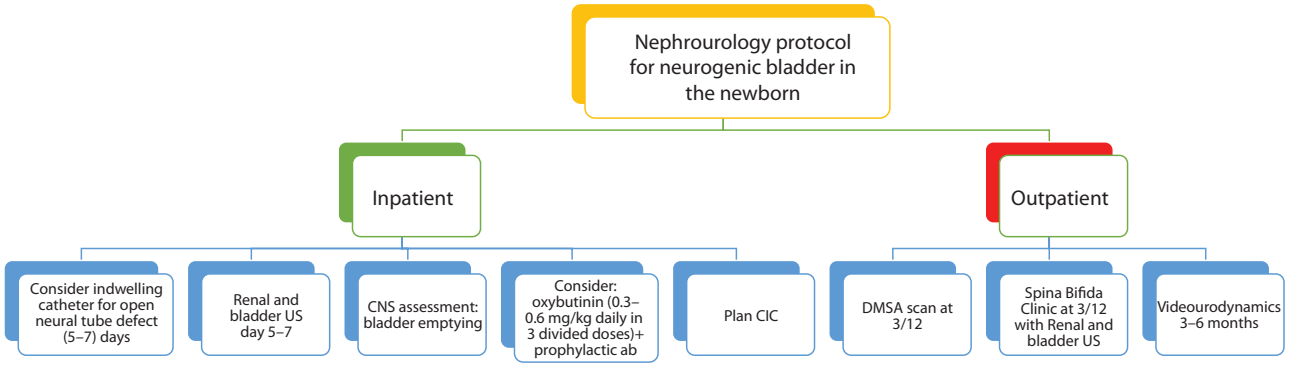

Figure 107.2 Nephrourology protocol for neurogenic bladder in the newborn.

videourodynamics according to circumstances. However, we would recommend to start in all patients daily CIC. This is neither to provide the patients with continence nor to improve bladder emptying. The CIC at this age in these patients is simply to ensure that the intervention is accepted by them, as it has been undertaken all their lives. This way, should problems become apparent during monitoring, or should the patient not develop continence in future years, the frequency of CIC can simply be increased, rather than having to go through the trauma of introducing the intervention in an older child and at a time when anxieties are raised in the family because of the child's problems.

Our preferred option for patients with open spinal defects is a *proactive* approach, as virtually all patients will have a neurogenic bladder. All the newborns are commenced, after their period of continuous catheterization, on CIC and antimuscarinic medication, to try and prevent obstructive uropathy and preserve renal function. We would also most often use prophylactic antibiotics, though there is no firm evidence base for these. The rationale for the CIC and antimuscarinic medication is based on published studies that, in the last 20 years, have shown a significant decrease in augmentation rate in patients treated proactively compared to expectantly.[9,10] In a nonrandomized prospective study, Edelstein et al.[11] found that 15% of the children treated with prophylactic intermittent catheterization had urinary tract deterioration versus nearly 80% of children followed by observation. A proactive approach is also recommended by a Dutch group, which has shown that 29 of their 65 initially "low-risk" patients later became high risk at a mean age of 3.1 years. The authors concluded that early start of CIC is essential to prevent renal damage.[12] In addition, on multivariate analysis, the late institution of CIC (after the age of 1 year) together with the presence of VUR and urinary tract infections (UTIs) has been found to be the only independent risk factor for renal cortical loss.[13]

Clean intermittent catheterization

In the management of a neurogenic bladder, CIC represents the most important modality to empty the bladder adequately and to protect the upper tract. Since its first description by Lapides in 1971, CIC has gained popularity over the years because it allows bladder emptying, avoiding any residue of urine in the bladder, thus reducing the risk of UTI and preventing the occurrence of high-pressure voiding, which is detrimental for kidney function. Even in neonates with lower motor neuron lesions, a good compliant bladder, and low leak point pressure, where CIC might be justifiably delayed, catheterization will be required at the time of toilet training to achieve continence. Our experience in patients with neurogenic bladder indicates that the early institution of CIC is better tolerated by the family and the child, becomes part of the family routine, and helps the parents to cope with their child's disease. The frequency of CIC, from twice to six times daily, will be decided on the basis of the videourodynamics (bladder capacity, activity of sphincter and detrusor, postvoid residual), fluid intake, and age of the child. Complications associated with CIC range from 0% to 40%.[14] Over a period of 16 years, approximately a quarter of boys encountered major complications following repeated catheterization, including false passages, meatal stenosis, urethral stricture, and epididymitis.[15] In young females with myelomeningocele, complications seem to be mainly difficulties in catheterization, macroscopic hematuria, and urethral polyp.[16] To prevent complications, the authors recommend early start of CIC, the use of lubricant (many modern single-use catheters are prelubricated now), and the catheterization with as large a catheter as possible that can be accepted into the urethra.

Pharmacologic treatment of neurogenic bladder overactivity

Oxybutinin hydrochloride is the only anticholinergic medication available for the treatment of neurogenic bladder in newborns and infants. It is available in liquid form, which allows easy titration according to the patient's weight; the recommended dose is 0.3–0.6 mg/kg per day in three divided doses. It is a smooth muscle relaxant, which acts by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by

acetylcholine released from activated parasympathetic nerves. There are five subtypes of muscarinic receptors (M1–M5) distributed in the body. In the human detrusor muscle, M2 and M3 subtypes are found, with M2 representing two-thirds of the total number and M3 mainly responsible for normal micturition contraction.[17] The mechanism of action of oxybutinin is due to a combination of antimuscarinic receptor antagonism, direct antispasmodic effect on the smooth muscle of the bladder, as well as local anesthetic action. The latter seems to be relevant only when oxybutinin is administered intravesically.[18] An experimental study in cultured rat bladder smooth muscle cells has also shown that oxybutinin chloride is involved in bladder remodeling by decreasing smooth muscle proliferation in a dose-dependent manner, helping to prevent permanent bladder changes.[19]

The wide distribution of the muscarinic receptors in the body, brain, heart, salivary glands, and smooth muscle explains some of the common side effects encountered with its use, which include dry mouth, tachycardia, constipation, blurred vision, dizziness, headache, hallucinations, agitation, confusion, and increased postvoid residual, which is not a problem for patients on CIC.[17] Newer antimuscarinic agents are targeted to mainly M3 receptors and therefore have a lower incidence of side effects. While not available for infants, yet they are being trialed in children.

Due to its high lipophilicity, neutral charge, and relatively small molecular structure, oxybutinin easily crosses the blood–brain barrier, which has raised concerns on the association between long-term use of antimuscarinics and cognitive dysfunction. However, a recent study on a small group of patients has demonstrated no significant differences in Child Behavior Checklist scores between children with spinal dysraphism on oxybutinin from birth onward and controls at a median age of 10.6 years.[20] Moreover, a randomized double-blinded trial using long-acting oxybutynin or tolterodine in children with urgency or urge incontinence has also found that long-acting oxybutinin and tolterodine had no negative effects on short-term attention and memory.[21]

The benefit of antimuscarinics in children with detrusor hyperreflexia secondary to neurogenic conditions has been demonstrated by Franco et al.,[22] who have shown an increase in bladder capacity (maximal cystometric capacity), decrease in mean detrusor intravesical pressures, and decrease in number of patients exhibiting uninhibited detrusor contractions. The improvement was consistent across the three formulations of oxybutinin available in the market, oral, syrup, and extended release.

Botulinum toxin injections

Intravesical botulinum toxin injections have been used effectively in patients with neurogenic bladder to eradicate overactive contractions and increase functional bladder capacity. Its primary effect on the bladder is to inhibit acetylcholine release from parasympathetic nerves. The botulinum toxin is administered by intradetrusor or submucosal injection during cystoscopy. The total patient dose is divided into a number of aliquots and injected in a fan array around the bladder, avoiding the trigone.

There are two preparations of botulinum toxin available: *Botox, Allergan (onabotilinum)*, and *Dysport, Ipsen (abobotulinum)*. For Allergan, the dose administered in neurogenic bladder is 5–10 units/kg, up to a maximum of 300 units. For Dysport, the dose is 15–30 units/kg, up to a maximum of 900 units. Botulinum toxin injections can be very effective and eradicate overactivity where antimuscarinic drugs have failed. To the authors' knowledge, there are no published studies showing the efficacy of botulinum toxin in the management of neurogenic bladder in the neonatal period. A recent analysis of 10 published studies with a total of 200 patients (mean age of 9.9 years) with neurogenic bladder mostly due to myelodysplasia has clearly demonstrated that botulinum toxin increases bladder capacity, decreases the maximal detrusor pressure, increases mean continence score, and improves bladder compliance in all patients.[23] Administered correctly, there are no systemic side effects. However, the effect wears off after 6–9 months. Because general anesthesia is mandatory for botulinum toxin injection in children, alternative routes of application have been tried such as intravesical instillation or electromotive drug administration (EMDA), but initial studies require confirmation, and appropriate catheters need to be sourced.[24]

A further use for botulinum toxin is for relaxation of a tight sphincter. In cases where the sphincter is tight or severely dyssynergic, leading to obstructive uropathy, injection of botulinum toxin into the sphincter can temporarily lower the leak pressure and avoid the need for a urinary diversion.

Urinary diversion—vesicostomy

In a small selected group of patients with neurogenic bladder, in whom conservative management fails, the formation of vesicostomy should be considered. It is a simple, well-tolerated, easily reversible procedure that is highly effective in reversing upper tract dilatation. Since its first description by Duckett in 1974, numerous reports have demonstrated an improvement in the upper urinary tract dilatation in 86%–100% of patients. Indications for surgical intervention include worsening hydronephrosis, progression of renal damage, high-grade VUR, or recurrent UTIs despite maximal medical therapy. Complications are encountered in 17%–43% of patients and include peristomal dermatitis followed by bladder prolapse, stomal stenosis, bladder calculi, and recurrent UTIs.[25]

Bladder augmentation and procedures to increase outlet resistance

Other surgical procedures such as bladder augmentation, bladder outlet procedures (periurethral injection of bulking agents, autologous fascial sling, implantation of artificial sphincter), and formation of catheterizable channels for CIC (Mitrofanoff or Monti channel) are rarely required in

the newborn period; therefore, their detailed discussion is beyond the scope of this chapter.

BOWEL MANAGEMENT

Spinal cord lesions affect colorectal motility, transit time, and bowel emptying, leading to constipation, fecal incontinence, or a combination of both.[26] Neurogenic bowel and bladder are closely related, and bladder symptoms correlate directly with bowel symptoms. Retained stools in the rectosigmoid can press over the bladder, impairing bladder filling, causing bladder instability, urgency, frequency, and incontinence. In addition, fecal soiling increases the risk of perineal colonization, bladder contamination, and UTI. In a neonate, bowel problems present as either constant loose stools due to complete absence of tone with a patulous anus or constipation. Constipation usually presents at around 4–6 months once solid feeds are introduced. Children with constant loose stool are at risk of excoriation of the buttocks and bleeding from the perianal skin. Barrier creams and exposing the skin to air will help. Constipation should be managed from an early age to promote cleanliness, to improve bladder dynamics, and to prevent UTIs. Early treatment with a high-fiber diet and oral laxatives (lactulose) may be sufficient in the first few years of life to soften the consistency of the stool. Glycerin and bisacodyl suppositories can be used to achieve bowel evacuation in children with an adequate rectal tone. In children with true fecal incontinence due to a deficient fecal continence mechanism and prolonged colorectal motility, mini washouts of water with either a syringe connected to a catheter or a cone-shaped tipped irrigation set can be used. A washout of 20 mL/kg tap water instilled by gravity, either daily or on alternative days, is recommended to ensure regular bowel emptying.

For children older than 3 years, different transanal irrigation systems are available in the market (Peristeen Coloplast LTD, Nene Hall, Peterborough Business Pk, Peterborough, United Kingdom; Irrimatic Pump, B. Braun Medical LTD, Thorncliffe Park, Sheffield, United Kingdom; Irrisedo Mini System, MBH-International A/S, Gydevang, 28-30, Denmark), which have been shown to be beneficial in 41%–100% of children with neurogenic fecal incontinence.[27] In older patients who fail medical therapy, an antegrade approach via the appendix to the cecum (Malone Antegrade Continence Enema [MACE] procedure) allows regular bowel emptying with improved social confidence, hygiene, and independence. Reported success rate as partial or complete fecal continence with MACE ranges from 47% to 100%,[28] with up to 80% of spina bifida patients recommending the MACE procedure to others.[29]

CONCLUSION

The management of a neonate with neurogenic bladder needs a multidisciplinary team with the urologist, renal/bladder physician, and neurosurgeon working together. The urology nurse specialist is central to the care of the patient. CIC is the most important part of the treatment and should be started as early as possible after birth and repair of the spinal defect. The main goal of therapy is not continence but protection of the upper tracts. The secondary aim is to try and ensure that the growing child has as good a bladder capacity and compliance as possible. Each patient is individual, and therapy needs to be tailored according to the findings in each child and the family circumstances.

Hydrometrocolpos

DEVENDRA K. GUPTA AND SHILPA SHARMA

INTRODUCTION

Hydrometrocolpos is a condition in which the uterus and vagina are grossly distended with retained fluid other than blood, usually in the presence of distal vaginal obstruction. The diagnosis and treatment of hydrometrocolpos has now been better streamlined as the condition is being diagnosed prenatally more frequently with the use of ultrasound and fetal magnetic resonance (MR) imaging.

Hydrometrocolpos presents at the two extremes of childhood, initially during the neonatal period, when there is a high level of maternal hormones, and then at early puberty, when the patient herself begins to have production of estrogenic hormones. The distal vaginal obstruction is mostly due to imperforate hymen (in two-thirds of cases) followed by a transverse vaginal septum, and less commonly, vaginal atresia (with or without persistence of a urogenital sinus or cloaca).

Associated anomalies are common and quite often of severe nature. These include anorectal malformations and unilateral or bilateral agenesis of the kidney/s, ureters, and trigone. Uterine anomalies like didelphys may also be associated, especially in cases with common cloaca. There are often back pressure changes in the urinary tract due to the pressure effect. The vagina may be bifid in a case of common cloaca, with the terminal bowel opening directly into the intervaginal septum or even at the base of the urinary bladder. Ultrasonography, micturating cystourethrogram (MCU), dye study through a vaginostomy, panendoscopy, and MR urography would help to evaluate the complex anatomy of hydrometrocolpos associated with genitourinary anomalies.

The main treatment of hydrometrocolpos is surgical. Medical management is required to build the nutrition of the baby and make her fit for surgery. The operative procedure and timing of surgical intervention depend upon the severity of the condition, type of anomaly, and age at presentation. Early surgery is indicated in the neonatal period when a grossly distended hydrometrocolpos presents with a bulging hymen, quite often associated with complications (abdominal mass, urinary obstruction, constipation, sepsis, dehydration). Laparotomy is indicated in patients with high vaginal obstruction and for the treatment of abdominal complications or associated anomalies.

The baby would need resuscitation and stabilization during the acute stage with antibiotics and intravenous (IV) fluids. A temporizing procedure like aspiration of the turbid infected fluid (or an abdominal tube or a flap vaginostomy) is indicated in the neonatal period to drain the infected material from the vagina. A percutaneous nephrostomy may also be needed in patients presenting with severe bilateral hydroureteronephrosis leading to urinary obstruction, uremia, and sepsis.

Hydrometrocolpos has been classified into five types on the basis of the type and level of obstruction (Figure 108.1).

I. Low hymenal obstruction
II. Midplane transverse membrane or septum
    a. Without communication
    b. With a small orifice as communication
III. High obstruction with distal vaginal atresia
    a. Without any perineal swelling
    b. With perineal swelling
IV. Vaginal atresia with persistence of the urogenital sinus
V. Vaginal atresia with cloacal anomaly

An algorithm for management of hydrometrocolpos has been suggested (Figure 108.2) [1]. Newborns presenting with complications should be managed in the intensive care unit with systemic antibiotics, IV fluids, decompression of gastrointestinal tract by nasogastric aspiration, and administration of oxygen. Fluid and electrolyte imbalance should be corrected. A Foley catheter should be inserted in the bladder for urinary drainage. In the presence of a huge distended hydrometrocolpos in a sick neonate, a preliminary drainage by puncturing the vagina under ultrasonographic guidance may be done for 24–48 hours prior to corrective surgery. Alternatively, the vaginal septum (type II anomaly) can be incised under ultrasonographic guidance safely or under vision in experienced hands.

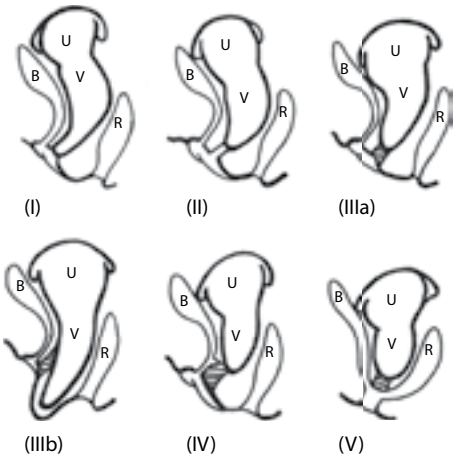

Figure 108.1 Classification. hydrometrocolpos with (I) hymenal obstruction, (II) low vaginal atresia, (IIIa) high vaginal atresia, (IIIb) high vaginal atresia with gluteal extension, (IV) urogenital sinus, and (V) common cloacal malformation.

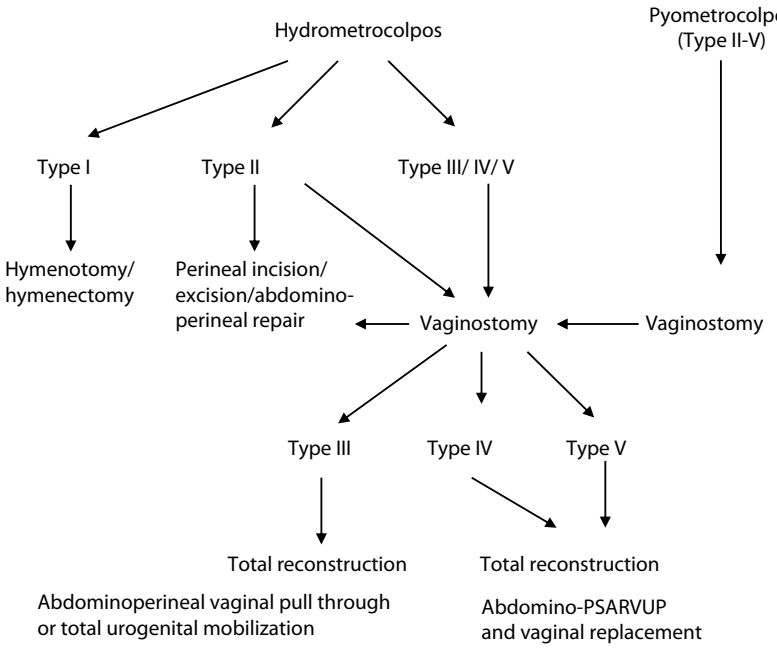

Figure 108.2 Algorithm for management of hydrometrocolpos. PSARVUP, posterior sagittal anorectal vagino-urethroplasty.

The management options depend upon the type of obstruction. Management is simple with low-level type I and II anomalies. However, patients with type III, IV, and V anomalies are usually obstructed and infected. Moreover, type IV anomaly has a valvular opening between the urethra and the vagina, allowing urine flow to the vagina during the act of micturition, and vice versa. In such cases, an attempt should be made to drain the infected material collected in the vagina by a suprapubic route (catheter or flap vaginostomy as a first-stage procedure) and allow the dilated vagina to shrink. This is followed by a definitive procedure (vaginal pull-through) later on (as a second-stage procedure). All previous attempts to drain the vagina and also simultaneously reconstruct the vaginal tract in the newborn stage carried a very high mortality, and it is thus not recommended.

DRAINAGE PROCEDURE

The advantages of an early drainage in neonates include drainage of the infected material to reduce sepsis, disconnection of the communication and retrograde flow of urine to the vagina, and allowing the inflamed vagina and uterus to shrink and occupy near-normal anatomical positions and size to allow planning of definitive surgery. In cases of common cloaca, a suprapubic cystostomy may serve to decompress the infected collection in the urogenital system. In prepubertal age, drainage allows natural passage for menstrual flow and

creation of a passage for future sexual activity and fertility. The drainage procedure through the perineum may be the only definitive treatment required in types I and II.

A bulging membrane in an infant with imperforate hymen or transverse septum of the vagina may be incised without anesthesia. However, excision is preferable if the hymen is thickened or the patient is an adolescent. Hymenotomy may resolve the acute renal failure caused by hydrometrocolpos. In all cases, it is desirable to maintain the patency of the opening by the initial use of a drain followed by repeated dilatations (Figure 108.3).

In the lithotomy position, the bulging hymen becomes visible as a grayish membrane. If necessary, the abdomen may be compressed to make the hymenal bulge more prominent. A Foley catheter is inserted into the urinary bladder to decompress it as well as for the identification of the urethra during the surgery. A series of stay sutures is placed at the center of the hymen, and the vaginal fluid is aspirated and sent for microscopic examination and culture (Figure 108.4b). A circular hymenal segment is excised using a no. 11 blade (Figure 108.4c). The cut margin is oversewn and retracted with vertical mattress sutures (Figure 108.4d). The sutures are tied, exposing the vaginal cavity (Figure 108.4e). A soft Silastic catheter is inserted into the vagina. A contrast study is performed to delineate the internal anatomy. The vagina is drained for a couple of days. This procedure is simple and can be performed at the bedside or in the intensive care unit in a sick baby after assessing the depth with a needle puncture and ultrasonography. In cases of doubt, the procedure may be done in the operating room safely through the abdominal route after performing a dye study. A Hegar dilator or a finger is placed through the vaginostomy opening as a guide, to remove a disk of the septum, which may be thick. The edges are then oversewn and a drain placed. Antibiotics should be given for 5–7 days postoperatively.

A vaginostomy serves as a temporizing drainage procedure for cases with infected fluid. It may be done through the perineal route in type II after confirmation of the diagnosis with a needle aspiration. When a low transverse vaginal septum is present (between the lower one-third and

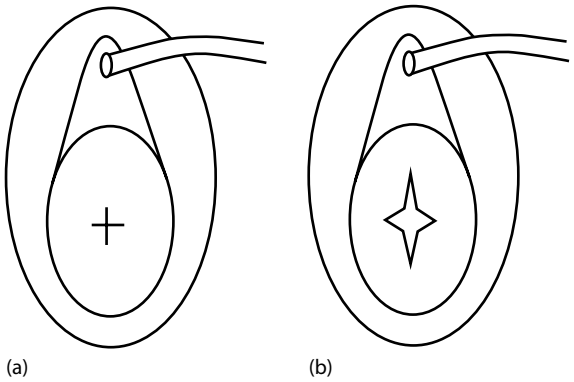

Figure 108.3 **(a** and **b)** Hymenotomy.

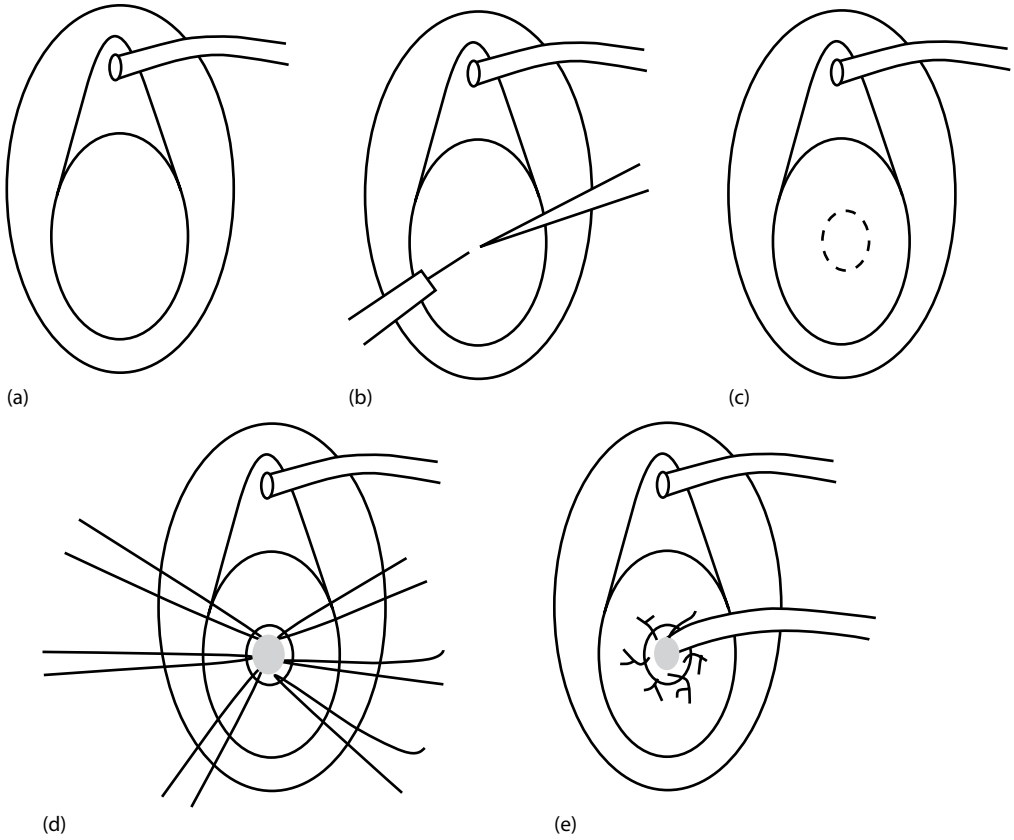

Figure 108.4 **(a–e)** Hymenectomy (with excision of the membrane disk).

upper two-thirds of the vagina), it presents as a bulging membrane, allowing its excision and permitting drainage by the perineal route (Figure 108.5a). In some patients, a minute vaginal orifice may be visible that may be surgically enlarged and oversewn with the placement of a catheter in the vagina for establishing drainage (Figure 108.5b).

However, even in type II anomaly, sometimes, due to secondary infection or complex anomalies, a perineal procedure may be deferred, and these babies may need suprapubic drainage by catheter or a vaginostomy. The proximal diversion stoma not only helps in decompressing the vagina but also provides a portal for detailed radiographic studies to delineate the anatomy. If the transverse septum in type II cases is more than 1 cm thick, it is wiser to perform a laparotomy and define the proper anatomy, incise the septum precisely under direct vision, and then drain the vagina. This is performed in order to prevent injury to the urethra and rectum during the perineal dissection.

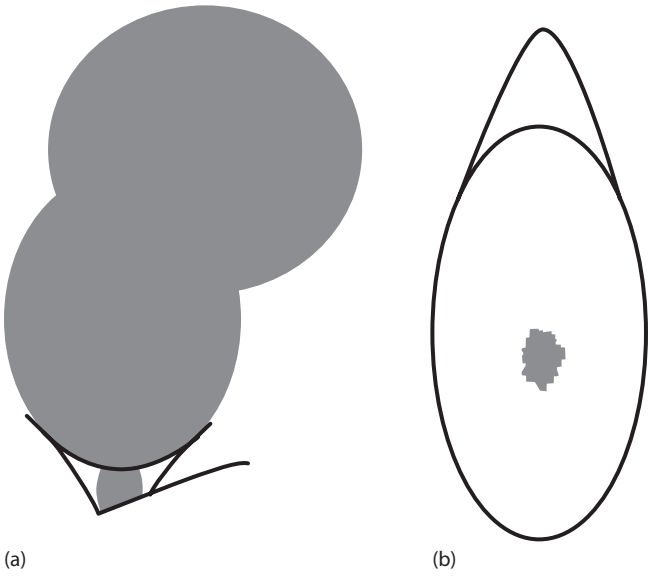

Figure 108.5 **(a** and **b)** Perineal vaginostomy.

Abdominoperineal repair of type II hydrometrocolpos is as follows: A low transverse abdominal incision is made (Figure 108.6a). The hydrometrocolpos is delivered from the abdominal wound, and a purse string suture is applied on the vaginal wall. Fluid is drained out (Figure 108.6b). A Kelly forceps is then introduced through the vaginostomy opening, and the tip is advanced toward the most dependent part of the dilated vagina in the perineum (Figure 108.6c). The vaginal septum is then incised while the outer vaginal orifice is spread open by the nasal speculum and the transverse septum is pushed downward by the Kelly forceps. The septum is incised, and the Kelly forceps is pushed down and out. A Silastic catheter drains the vagina from below (Figure 108.6d). The hydrometrocolpos is also drained by an indwelling catheter from above for 5–7 days (Figure 108.6e).

For types III–V, hydrometrocolpos with atresia of the lower two-thirds of the vagina or in a case of common cloaca with hydrometrocolpos, an abdominal route is preferred for doing the vaginostomy. If the atretic lower portion of the vagina has been retracted up into the pelvis, it may be desirable to open the vagina through a laparotomy incision to avoid damage to the urethra, bladder, and rectum.

Abdominal vaginostomy may be of two types: vaginostomy with an indwelling catheter and tubed vaginostomy. The abdomen is opened with a Pfannenstiel incision. The dilated vagina is identified, and stay sutures are applied. The steps as described in Figure 108.6a–c remain the same.

1. *Vaginostomy with an indwelling catheter (Figure 108.7a–e).* Though it is easy to perform, it has certain disadvantages like infection, encrustation, and also the need to

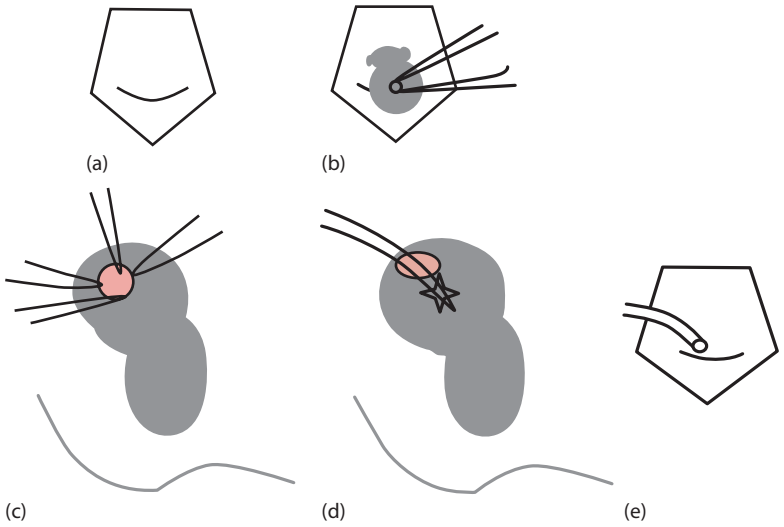

Figure 108.6 **(a–e)** Abdominoperineal repair (combined approach).

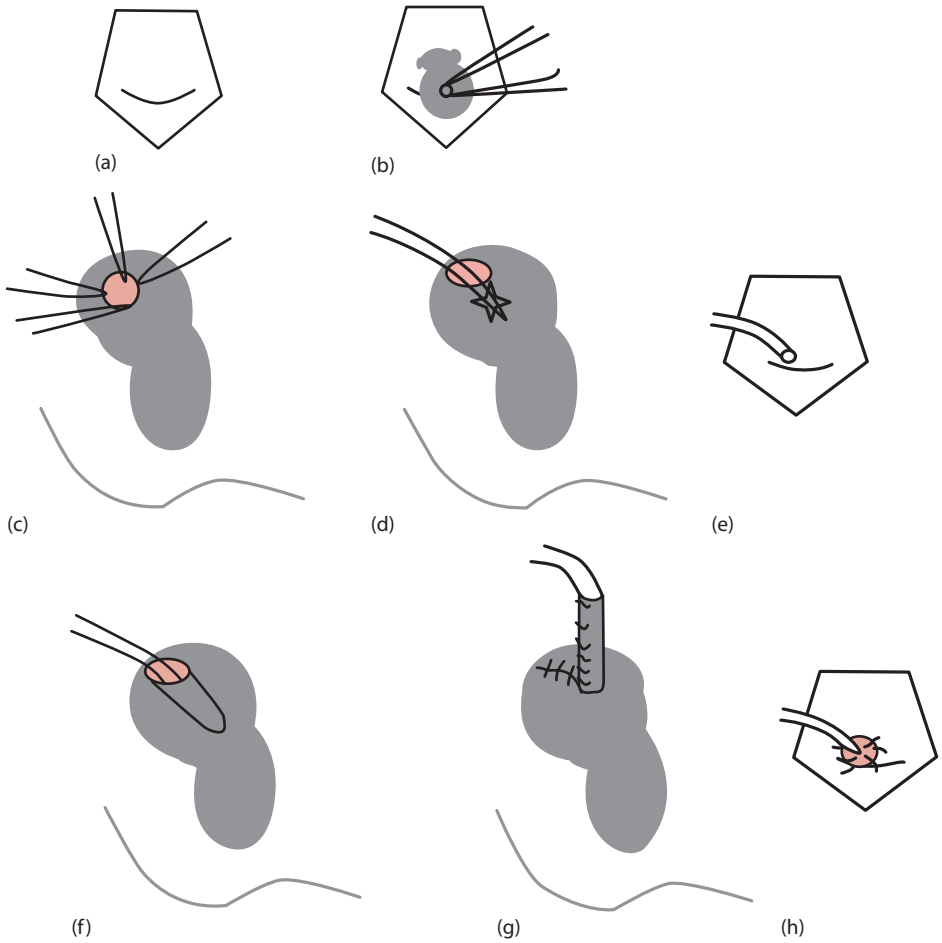

Figure 108.7 **(a–e)** Operative steps for abdominal vaginostomy. **(a)** Pfannesteil incision. **(b)** Stay sutures are applied on the distended vagina. **(c)** Opening in vagina is brought out and stitched to abdominal wall all around in two layers. **(d)** Malecot catheter is placed in the distended vagina. **(e)** Abdominal wound closed in layers. **(f–h)** Operative steps for tubed vaginostomy **(f)** A U-shaped flap is created with the vaginal wall. **(g)** Flap is closed in a cylindrical manner to form a tube of the vaginal wall. **(h)** Vaginal tube is brought out of the abdominal wall as a stoma. A catheter is left in for few days.

keep the tube in situ, requiring frequent changing and causing an inconvenience to the patient.

2. *Tubed vaginostomy (Figure 108.7f–h).* In this procedure, a U-shaped flap of the vagina is used to make a tube that provides drainage through the natural tract (rather than the need for a catheter) till the time of definitive surgery. The U-shaped incision is seen in Figure 108.7f. It is made into a tube, as shown in Figure 108.7g. The edge of the tube is fixed to the abdominal wall and the skin, as shown in Figure 108.7h. A tubed vaginostomy avoids the long-term use of any indwelling catheter and at the same time provides an effective drainage. This also provides easy access for performing dye studies to outline the anatomy before doing a definitive surgery.

Cases of type V hydrometrocolpos (associated with common cloaca) and a common channel more than 3 cm long require a vaginostomy and also a diverting colostomy. This is to be done keeping the good segment of the sigmoid bowel available for both vaginal replacement and bowel pull-through in the future. Thus, a transverse colostomy is preferred (Figure 108.8).

In type IV, if the common channel of the urogenital sinus is less than 2.5 cm long, as confirmed by endoscopy

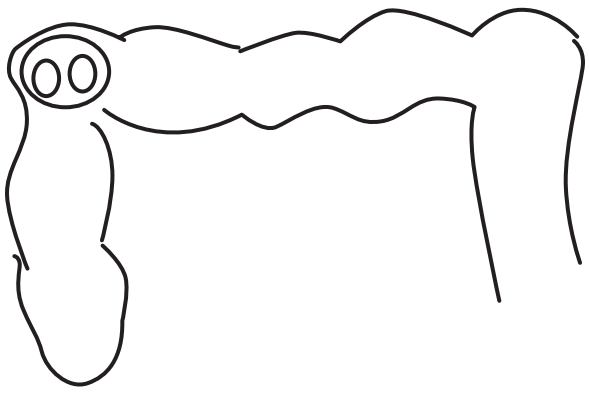

Figure 108.8 Transverse colostomy for common cloaca.

at surgery, disconnection of the fistula is done followed by total urogenital mobilization. The vagina may be exteriorized onto the perineum, while the urogenital sinus can be made to function as the main urethra. The patient is placed in lithotomy position (Figure 108.9a). Stay sutures are applied around the urogenital sinus such that the sutures lie within the line of incision (Figure 108.9b). An incision is made all around the urogenital sinus with a midline posterior incision in the sinus that extends posterolaterally in the perineum for adequate exposure and mobilization (Figure 108.9c). As the meticulous dissection continues, the urethra and the vagina become visible externally as two separate openings, and the tissues are approximated (Figure 108.9d). If the vaginal introitus is narrow, it can be widened by placing a Barrow's skin pedicle flap in its posterior wall. At times, the vagina may open into the bladder as a fistulous communication.

However, if the length of the urogenital sinus is more than 2.5 cm, then vaginal replacement would be required. The fistulous communication between the urethra and the vagina cannot be reached through the perineum. It is divided repaired with sutures, and the vagina is brought to the perineum by using the posterior sagittal route, bisecting the rectum to approach the vagina directly from behind (PSARVUP). An additional abdominal route is also required for vaginal replacement.

This is a major undertaking, and to achieve the best results, the procedure should be performed by a team of experienced surgeons preferably in a tertiary care–level center.

The common channel in type V is usually more than 3 cm, mandating a vaginal replacement. In cases with type III, IV, and V with pyometrocolpos, it may be difficult to separate it from the surrounding structures due to severe inflammation and dense adhesions. In such situations, it would be better to replace the vagina using bowel vaginoplasty. A loop of sigmoid colon or an ileum can be used for bowel vaginoplasty. An abdominoperineal approach is adopted. The abdomen is opened with a Pfannenstiel incision with extension on the left side in a hockey-stick manner (Figure 108.10a). The vaginal space is created in the perineum carefully between the

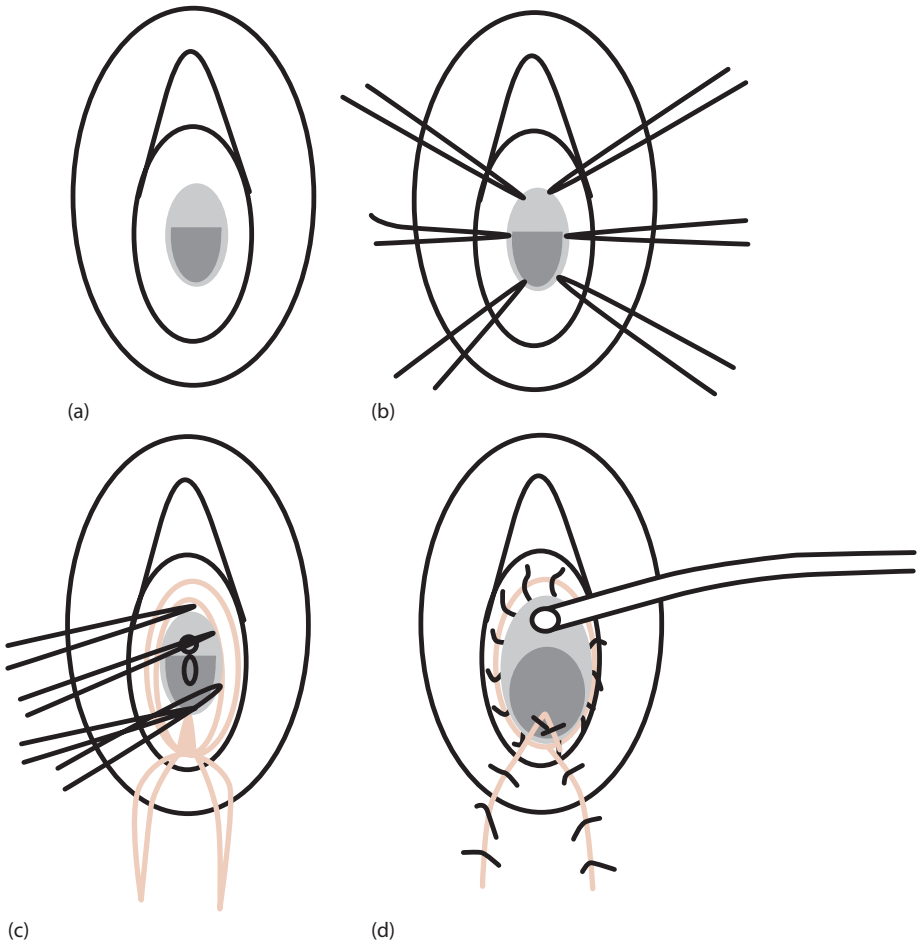

Figure 108.9 Total urogenital mobilization (TUM). **(a)** Diagrammatic representation of the urogenital sinus. **(b)** Stay sutures are applied all around the urogenital sinus in such a manner that an incision can be given around them. **(c)** Mobilization of the urogenital sinus is done along with a midline posterior incision or an inverted V-shaped incision (Barrow's flap). **(d)** After adequate mobilization, the urethral and vaginal openings may be visualized on the surface as two separate openings. The barrows flap if created may be used to widen the vaginal orifice.

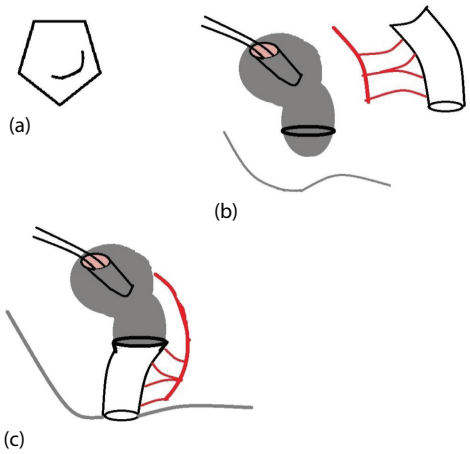

Figure 108.10 **(a–c)** Vaginal replacement with bowel segment.

rectum and the urethra and also from the abdominal side. The length of the bowel required for vaginal replacement is assessed. An adequate length of the colonic bowel segment on its mesentery with adequate blood supply is selected for the pull-through (Figure 108.10b). The upper end is anastomosed to the proximal vagina from the abdominal side, and the distal end of the bowel is anastomosed to the perineal skin at the proposed vaginal introitus, taking care not to cause any torsion to the bowel segment or traction on the blood supply (Figure 108.10c).

In cases with a narrow distal vagina or if the vagina has retracted following its repair, flaps of perineal skin may be used to contribute to the distal vaginal segment. A Barrow flap is the most commonly used procedure. An inverted-Y incision is made, with the vertical limb of the *Y* going inside the vaginal introitus for a centimeter or so in the posterior wall (Figure 108.11a). With the V-shaped perineal skin intact, blood supply is created and mobilized sufficiently. It is then advanced in the vagina and sutured to the margins of the incision edges in the introitus (Figure 108.11b).

Many surgeons prefer the use of a skin graft over a vaginal mold, a cylinder of a prosthetic patch, or a buccal mucosa graft with a mesh to form the neovagina. The results are variable, and retractions and graft contraction are not uncommon. Expertise is needed to perform such a surgery. This kind of replacement is better performed at puberty or before marriage, as it is prone to shrinkage and needs repeated dilatations.

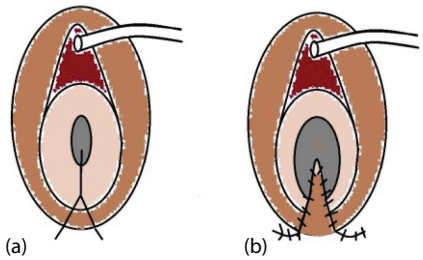

Figure 108.11 **(a** and **b)** Barrow flap vaginoplasty.

SUMMARY

Hydrometrocolpos is a rare disorder. From a clinical point of view, there are three groups:

1. Low anomalies, usually presenting in the newborn period with a hymenal obstruction (rarely the distal vaginal obstruction) and a bulge in the perineum. The diagnosis is made on inspection and needle aspiration of the contents from the bulge under anesthesia. The contents are normally clear. A perineal incision in the bulge is curative. Though no detailed investigations are required in early infancy, the associated genitourinary anomalies should be ruled out with ultrasonography and IV pyelogram or an MR urography in due course.
2. Hydrometrocolpos with urogenital sinus anomaly. In such cases, there are two openings in the perineum instead of three: the urethra and the anus. The vagina is high up and has a tiny communication with the urinary bladder, usually at the level of the bladder neck. This communication is valvular and allows only one-way flow of urine from the urinary bladder to the vagina. A small amount of urine flows into the vagina during the act of micturition, but the vagina cannot drain it to the urethra due to the valvular effect; thus, there is slow development of hydrometrocolpos. Due to stasis of urine and the vaginal contents, the hydrometrocolpos gets infected, resulting in pyometrocolpos, and the child presents with septicemia. It is mainly the vagina that gets dilated; the uterus, not so much. The genitourinary tract is often obstructed due to the effect of pressure, and there is a bilateral hydroureteronephrosis. The patient presents in an emergency with a palpable lump in the lower abdomen, urinary obstruction, sepsis, uremia, and bilateral hydroureteronephrosis. Urgent investigations with ultrasonography, MR urography, and biochemistry are performed, and the patient is stabilized with fluids and antibiotics. The dirty fluid needs to be drained out urgently using a catheter or by fashioning a formal tube vaginostomy by the suprapubic route. Final surgery, usually after the age of 1 year or so, would require closure of the communication of the channel from the bladder and a vaginal pull-through. It is easier said than done because the vaginal walls are inflamed, thickened, and plastered to the surrounding pelvic structures, and it is not possible to mobilize them to bring them down to the perineum. Thus, it is safe to perform a vaginal replacement and bridge the gap using a segment of the colon or ileum.
3. Hydrometrocolpos with cloacal malformation. This is the most serious of all anomalies in this group. The patient has only a single opening in the perineum, into which open the urethra, the vagina, and the bowel. The

confluence is high up at the bladder neck. The vagina may be bifid with a complete or incomplete septum in between with each half of the uterus. The vagina becomes dilated so that urine can flow through the fistula. The bowel is opened with a fistulous tract either in the vaginal septum or in the bladder neck. In some cases, the whole of the colon is turned into a cesspool-like structure, called a pouch colon, having an abnormal vascular configuration. Surgery is required in the newborn period in emergencies for high-level types of anorectal abnormalities, urinary obstruction, and abdominal lump (hydrometrocolpos or pouch colon) in the form of a transverse colostomy (even ileostomy with the excision of pouch colon), closure of the fistula between the bowel and the bladder, and suprapubic tube vaginostomy to drain the vaginal contents. A urinary catheter drains the bladder well. After a year or so, the definitive surgery requires closure of the fistula between the vagina and the bladder, vaginal replacement with a segment of the bowel, a bowel pull-through with a complex reconstructive procedure by an abdomino-perineo-sacral route, called the posterior sagittal anarectal vaginourethroplasty (PSARVUP). Separation of the thick-walled vagina from the urinary bladder is tricky. A part of the vaginal wall adherent to the base of the urinary bladder can be left in situ, and the fistula can be closed to prevent damage to the urinary bladder. This should only be performed in a tertiary care–level setup by a team of experienced surgeons familiar with the anatomy and the surgical techniques.

Disorders of sexual development

MARIA MARCELA BAILEZ

INTRODUCTION

Patients with ambiguous genitalia mostly present in the newborn period requiring a multidisciplinary team, which includes a pediatric surgeon/urologist to assign the sex of rearing as soon as possible after a thorough genetic, anatomic, functional, and socioeconomic workup.

The diagnosis of *ambiguous genitalia* is based on a meticulous perineal exam and gonadal palpation.

The feminine phenotype presents a normal-looking clitoris and no palpable gonads.

The masculine phenotype presents a normal-looking penis and two scrotal testicles.

Although exceptions to this pattern occur, e.g., a female with an inguinal hernia or a male with a mild hypospadias or an undescended testicle; if a combination of abnormal gonadal palpation and external genitalia appearance is detected, sexual ambiguity should be studied. Isolated severe defects like a perineal hypospadias or bilateral nonpalpable gonads in a patient with a normal-looking phallus should also be investigated (Figures 109.1a,b and 109.2).

The Consensus Statement on Management of Intersex Disorders proposes the term *disorders of sex development* (DSDs), defined as congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical. Occasionally, patients with previously unrecognized DSD present later in infancy or puberty. The history of DSD management shows how, in the past, the recommendations for gender assignment of infants with ambiguous genitalia have been guided by the phenotypic appearance of the genitalia. The sex of rearing was mainly decided on the basis of what was believed would facilitate the "most functional genitalia and offer the child their best opportunity to reach normality" (Hughes et al. 2006).

The assumption was that the sex assignment would later determine the child's future sexual identity. However, this simplistic approach did not always work. More recent studies have helped us to better understand what actually determines gender identity, but even now, there is a paucity of outcome data for evidence-based approaches to these rare disorders.

Contemporary management sees DSD decision making as multifaceted, involving many different factors (none to the exclusion of the others), including etiology, fertility, and most likely gender outcome. Data coming from existing studies present conflicting outcomes. New scientific acquisitions unveil the ever-evolving complexities of the neurobiological and psychosexual development regarding gender identity.

ETIOLOGY

Sex differentiation refers to the anatomic development of the internal and external genitalia as male or female dependent on the presence or absence of functioning androgens.

Genital development is constitutively female and nondependent on estrogens prenatally. In contrast, male sex differentiation is mandatorily androgen dependent and requires optimal ligand activation of the androgen receptor (AR).

Gonad development

Fifteen years have passed since the discovery of Sry as the primary "testis-determining gene" (Jager et al. 1990; Blecher and Erickson 2007) in the classic experiment of Koopman et al. showing that transgenic expression of Sry in XX mice results in testis development and male phenotype. Studies in mice are continuing to provide exciting information about differential structural changes and gene expression in normal gonad development (testis versus ovary) as well as the effect of targeted deletion of key genes involved in this process. WT1, SF1, SOX9, DHH, DMRT, SIDDT, and ARX are some of the genetic determinants of normal gonad development and gonadal dysgenesis.

Androgens

The production of androgens by fetal Leydig cells is initially gonadotropin independent. Placental human chorionic gonadotropin (HCG) is the one that ensures high

(a)

(b)

Figure 109.1 **(a)** A newborn with bilateral nonpalpable gonads but a normal-looking phallus. **(b)** Classic hyperpigmentation seen in congenital adrenal hyperplasia patients before treatment, with severe defects like a perineal hypospadias and bilateral nonpalpable gonads.

Figure 109.2 Sexual ambiguity should be studied in a patient with combined abnormal gonadal palpation and external genitalia appearance.

concentrations of androgens during the first half of gestation to stabilize Wolffian duct development and differentiation of the external genital anlage. Wolffian duct stabilization is dependent on high local concentrations of testosterone diffusing in a gradient along the duct from the adjacent ipsilateral gonad. This accounts for the asymmetric development of Wolffian ducts in some DSDs.

The androgen receptor (AR) is a transcription factor that mediates male sexual differentiation in utero and is responsible for the development and maintenance of male sexual characteristics. The AR gene is located on the X chromosome. Mutations in the AR gene may lead to diseases like androgen insensitivity syndrome (AIS). In AIS, gonadal males had a spectrum of abnormalities ranging from individuals with a female phenotype (complete AIS [CAIS]) through genital ambiguities in the partial form (partial AIS [PAIS]) to men with fertility disturbances in minimal AIS (MAIS). More than 500 mutations have now been documented in AIS.

In summary, circulating testosterone is responsible for virilization and is dependent upon 5-RD2 (transforms testosterone into dihydrotestosterone) and the presence of appropriate receptors.

Anti-Mullerian hormone

The pre-Sertoli cells secrete a glycoprotein hormone called anti-Mullerian hormone (AMH). It causes involution of the Mullerian ducts and stimulates the Leydig cells to produce testosterone. It is also responsible for the first stage of testicular descent.

The AMH receptor is different from de the. Persistent Mullerian structures in 46,XY DSD patients may be due to failure of the production of the hormone from the testes (50%) or to receptor deficiency.

Steroids

Problems in the early stages of steroid genesis can result in abnormalities of adrenal steroid synthesis, which may result in external virilization of a gonadal female-like adrenal hyperplasia (congenital adrenal hyperplasia [CAH]) or underandrogenization of the 46,XY fetus.

21-Hydroxylase is encoded by a gene on chromosome 6. Its deficiency is inherited in an autosomal recessive fashion.

Tremendous progress has been made in the past 15 years in understanding the role of mutation of factors involved in the steroid genesis process (e.g., STAR, CYP11A, HSD3B2, CYP17).

Considerably more research is needed to be able to translate this new knowledge into effective patient care and to understand the long-term outcome in specific conditions.

HISTORY

The term *intersex* was used till 2005, and subcategories included male pseudohermaphrodite, female pseudohermaphrodite,

and true hermaphrodite. These terms used gender in the nomenclature and were often considered controversial or disparaging.

Therefore, revised nomenclature was proposed that incorporated genetic etiology and descriptive terminology while removing gender references.

The Lawson Wilkins Pediatric Endocrine Society (LWPES) and the European Society for Paediatric Endocrinology (ESPE) considered it timely to review the management of intersex disorders from a broad perspective, to review data on longer-term outcome, and to formulate proposals for future studies.

Advances in identification of molecular genetic causes of abnormal sex with heightened awareness of ethical issues and patient advocacy concerns necessitate a reexamination of nomenclature. Terms such as *intersex*, *pseudohermaphroditism*, *hermaphroditism*, *sex reversal*, and gender-based diagnostic labels are particularly controversial. These terms are perceived as potentially pejorative by patients and can be confusing to practitioners and parents alike. The ideal nomenclature should be sufficiently flexible to incorporate new information yet robust enough to maintain a consistent framework.

Terms should be descriptive and reflect genetic etiology when available, and accommodate the spectrum of phenotypic variation. Clinicians and scientists must value its use, and it must be understandable to patients and their families.

The Consensus Statement on Management of Intersex Disorders proposes the term *disorders of sex development* (DSDs), as defined by congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical.

PHYSICAL EXAMINATION

External genitalia exam includes the gonadal palpation and perineal exam; both are the key to choosing the sequence of diagnostic procedures to reach an etiologic diagnosis.

The visualization of both faces of the phallus, looking for the urethral orifice, and defining its localization and aspect are important. Inguinal and perineal palpation to look for gonads is the other diagnostic key.

Each patient needs to be considered on an individual basis.

PRESENTATION

Traditionally, DSD patients were classified into three groups based on gonadal structure:

1. Presence of two well-defined ovaries with ambiguous or male external genitalia (female pseudohermaphroditism, now called overvirilized XX female). These patients have a 46,XX karyotype, and virilization of the external genitalia results from exposure to a high level of androgens in utero while they have female internal genitalia. Congenital adrenal hyperplasia (CAH) is the most common disease in this group and accounts for 50%–80% of all the cases of ambiguity, depending on the population analyzed. The most common enzymatic defect is 21-hydroxylase deficiency. The incidence of 21-hydroxylase deficiency is 1 in 15,000–40,000 newborns. Other defects are 11-hydroxylase (hypertension) and 3-b-ol dehydrogenase or aromatase.
2. Presence of two well-defined testicles with ambiguous or female external genitalia (male pseudohermaphroditism; now called undervirilized XY male). These patients have a 46,XY karyotype, and ambiguity of the external genitalia results from a failure of the masculinization androgenic action of the male fetus. This can be due to a failure in androgenic synthesis or in the biological response. This group includes rare defects of the biosynthesis of testosterone, defect of 5-RD2 (enzyme that converts testosterone into dihydrotestosterone), and PAIS (partial defect of androgenic receptors). It is important to recognize that patients with a 46,XY karyotype and dysgenetic testicles are sometimes included in this group in the literature.
3. Presence of incomplete differentiated gonads or coexisting ovarian and testicular tissue with ambiguous or female external genitalia. This is a heterogeneous group with one common factor, which is a structural defect in gonadal differentiation with or without a chromosome alteration. Patients with mixed gonadal dysgenesis (MGD), testicular dysgenesis, and true hermaphroditism (TH, now called ovotesticular disorder of sexual development) are included in this group.

For the purpose of investigation, they are divided into the following:

1. Disorders of chromosomes (chromosomal DSD)
2. Disorders of gonad development (gonadal DSD, sex determination)
3. Disorders of sex steroid synthesis and action (phenotypic/anatomic DSD, sex differentiation)

DIAGNOSIS

According to the Consensus Statement on Management of Intersex Disorders, optimal clinical management of individuals with DSD should comprise the following: (1) gender assignment must be avoided before expert evaluation in newborns; (2) evaluation and long-term management must be performed at a center with an experienced multidisciplinary team; (3) all individuals should receive a gender assignment; (4) open communication with patients and families is essential, and participation in decision-making is encouraged; and (5) patient and family concerns should be respected and addressed in strict confidence.

The initial contact with the parents of a child with a DSD is important, because first impressions from these

encounters often persist. A key point to emphasize is that the child with a DSD has the potential to become a well-adjusted, functional member of society. Although privacy needs to be respected, a DSD is not shameful. It should be explained to the parents that the best course of action may not be clear initially, but the health care team will work with the family to reach the best possible set of decisions under the circumstances. The health care team should discuss with the parents what information to share in the early stages with family members and friends. Parents need to be informed about sexual development.

A detailed personal and familiar anamnesis can give important information. Some of these pathologies recognize a sex-linked transmission (X link), and the mother will be able to transmit the defect to 50% her male children (complete or partial androgen insensitivity). Many have an autosomal recessive transmission (CAH, deficit of testosterone synthesis, deficit of 5-RD2, deficit of the lutein hormone (LH) receptor).

The finding of a neonatal death in the first days of life of male babies may be due to an unrecognized congenital adrenogenital syndrome.

Still, diagnostic algorithms are useful as guidelines to simplify the study of these complex patients.

Figure 109.3 lists the sequence of investigations used in a newborn with a suspected DSD, according to gonadal palpation.

A karyotype is mandatory, but this always requires a few days.

In the absence of palpable gonads, the first blood test are those to exclude problems that can put life at risk (blood electrolytes), commonly found in the event of salt-losing CAH. The blood sexual steroids must be determined, and among them, the level of 17-OH-progesterone, which if elevated, will make it possible to diagnose the most common cause of DSD.

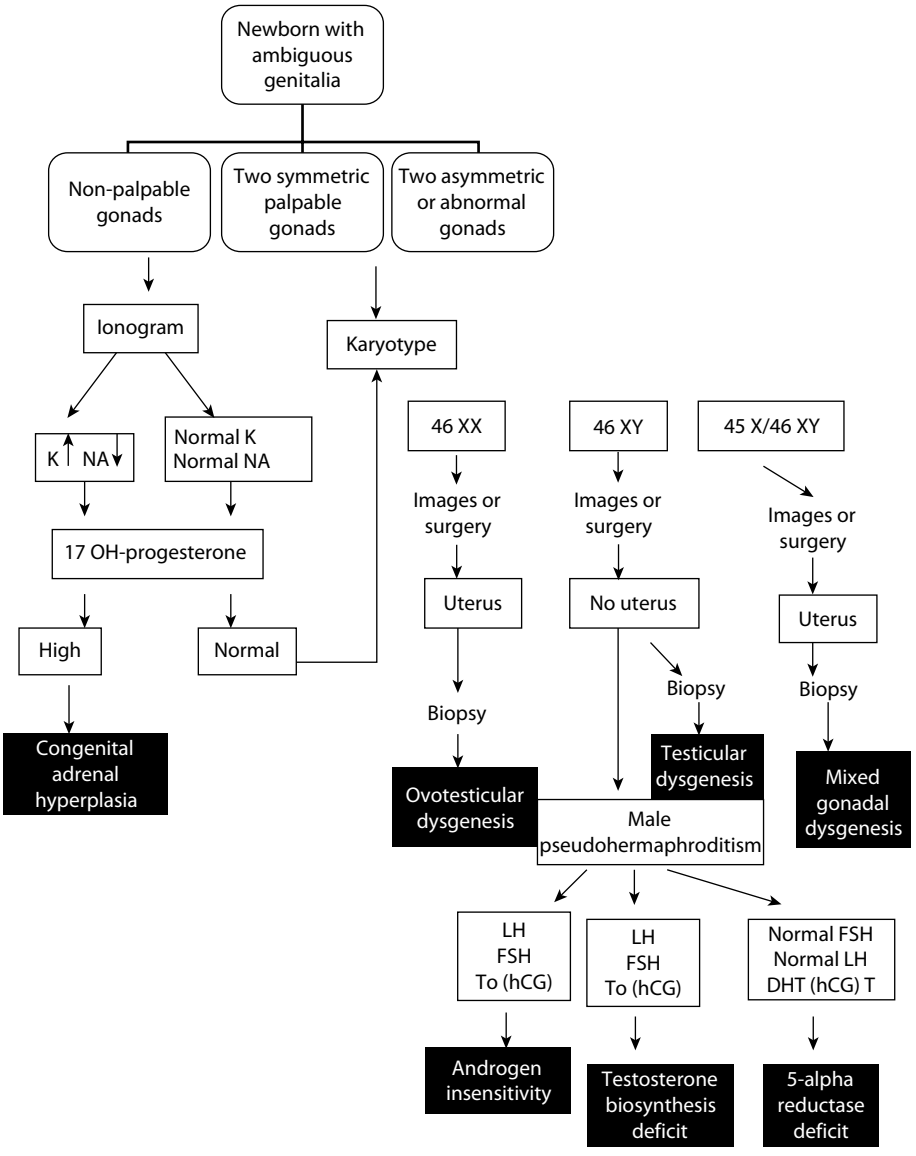

Figure 109.3 Sequence of investigations used in a newborn with a suspected disorder of sex development.

The dosage of other steroids (testosterone, dihydrotestosterone, delta-4-androstenedione, dehidroepiandrosterone [DHEA], 17-OH-pregnenolone), adrenocorticotrophine (ACTH), cortisol, and renin, will allow us to get a precise picture of the gonadal and adrenal steroidogenesis. For example, a testosterone/dehidrotestosterone (T/DHT) ratio with a value larger than 10 is suspicious for a deficit in 5-RD2 enzyme.

The most valuable stimulation tests for evaluating steroid genesis are as follows:

- HCG test for the study of testicular functionality.
- ACTH test for the study of adrenal steroid genesis.
- Low values of testosterone can be a sign of testicular dysgenesis if associated with low levels of all the other testicular steroids or of an enzyme defect of the steroid genesis path if they are associated with high levels of their precursors.
- Normal or elevated levels of T and DHT may be suggestive of a receptor resistance to androgens.
- The possibility of the ambiguous genitalia virilizing can be estimated after an HCG test or an appropriate stimulation trial with testosterone or topical DHT. This can be estimated by demonstrating the increment of the penile dimensions or indirectly by the dosage of androgen-sensitive circulating substances. Its value is reduced if the patient tissues present sensitivity for the virilizing effect of androgens.

Molecular biology techniques are more sensitive, and specific tests for assessment of the tissue sensitivity to androgens are not always available.

Histology is only required for diagnosis in patients with abnormal gonads (group 3).

Imaging tests

The primary objective of these tests is the study of the internal genitalia anatomy. The pelvic ultrasound for the demonstration of the presence of Mullerian structures is an important diagnostic element.

Genitography is very useful for the study of vaginal morphology, dimension, and relation to the urethra (Figure 109.4a,b,c). We look for the onset of the vaginal outlet in the urogenital sinus (UGS) with special attention to the proximal urethra to plan the urogenital reconstruction (see surgical treatment below).

Sex of rearing

Factors that influence gender assignment include diagnosis, genital appearance, surgical options, need for lifelong replacement therapy, potential for fertility, views of the family, and sometimes, circumstances relating to cultural practices.

More than 90% of patients with 46,XX CAH and all patients with 46,XY CAIS assigned female in infancy identify as females. Evidence supports the current recommendation to raise markedly virilized 46,XX infants with CAH as female. Still, around 5% develop gender dysphoria and have more chances of homosexualism and bisexualism—1%–3% transsexuals. A consistent penile development constitutes a basic element for the male choice of rearing even if today, the criteria that must guide this choice are object of debate.

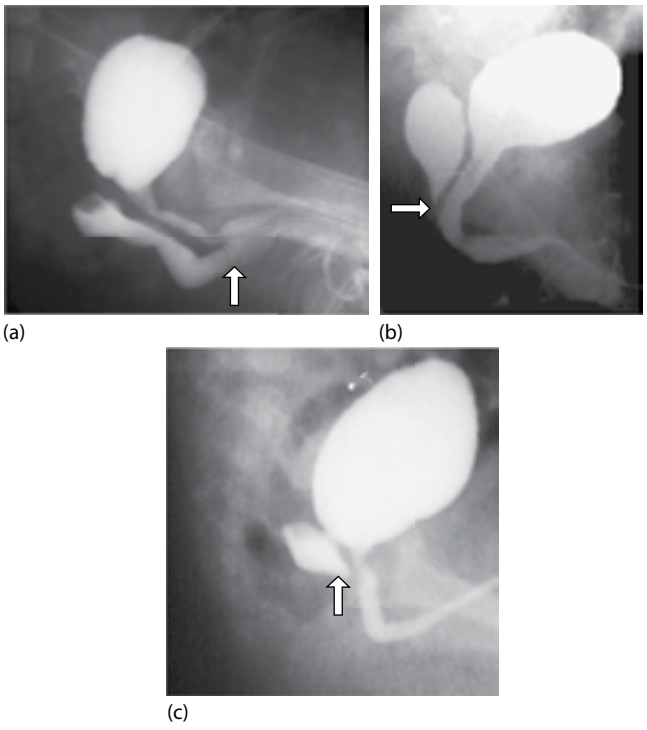

Figure 109.4 Genitography is very useful for the study of vaginal morphology, dimension, and relation to the urethra. Depending on vaginal confluence in the urogenital sinus, the vagina was classified as **(a)** low, **(b)** intermediate, or **(c)** high variant. The white arrows show the confluence of the vagina in the urogenital sinus.

A good response in testosterone levels after HCG test and an increase in penile length after administration of testosterone in neonatal age will be useful in making the choice of male sex.

In some patients, the possibility of future virilization at puberty has to be taken into account (deficit of 5-alpha-reductase and the defect of synthesis of testosterone). Nowadays, diagnosis is easier due to the aim of molecular genetics.

Approximately 60% of 5-alpha-reductase (5-RD2)–deficient patients assigned female in infancy and virilizing at puberty (and all those assigned male) live as males. In 5-alpha-reductase and possibly 17-hydroxysteroid dehydrogenase deficiencies, for which the diagnosis is made in infancy, the combination of a male gender identity in the majority and the potential for fertility (documented in 5-RD but unknown in 17-hydroxysteroid dehydrogenase deficiencies) should be discussed when providing evidence for gender assignment.

Among patients with PAIS, androgen biosynthetic defects, and incomplete gonadal dysgenesis, there is dissatisfaction with the sex of rearing in 25% of individuals whether raised male or female.

Available data support male rearing in all patients with micropenis, taking into account equal satisfaction with assigned gender in those raised male or female without need for surgery and the potential for fertility in patients reared male.

Those making the decision on sex of rearing for those with ovotesticular DSD should consider the potential for fertility on the basis of gonadal differentiation and genital development and assuming that the genitalia are, or can be made, consistent with the chosen sex.

In the case of MGD, factors to consider include prenatal androgen exposure, testicular function at and after puberty, phallic development, and gonadal location.

MANAGEMENT

Except for gonadal biopsy or resection, no other surgery is performed in the neonatal period. Most of the reconstructive procedures, although done early, are not recommended before the first month of life.

Evolution of practice in the last years tends to postpone surgery. Sex assignment does not mean inevitable surgical intervention. Each case needs to be considered in its own terms. Preservation of tissue, particularly gonadal tissue, and maintenance of the integrity of the body as whole are aspects of care and receive higher priority.

The surgeon plays an important initial role in the interdisciplinary group that an institution is obliged to have to take care of these complex patients. He/she needs to not only take care of the best operative techniques for better functional results but also manage the proper information (after conscious discussion of the group) to be given to parents and family. The use of improper words and misinformation may result in irreversible sequelae. In our opinion, the surgeon has to be very well informed and participate actively in the preoperative workup before making contact with the family.

- **Preoperative:** A stable endocrine status, especially in CAH patients, is highly important for a well-tolerated surgical procedure and better postoperative results. The psychosocial analysis of the family is also advised. Once again, we emphasize the interaction with the clinical colleagues in charge of them. When reconstructing the UGS, a preoperative enema is indicated. Preoperative antibiotics are used according to each institution's protocols.
- **Operative:** The role of surgery consists in the following: (1) gonadal treatment, (2) feminizing genitoplasty, and (3) urethral/penile reconstruction in the undervirilized child.

Gonadal treatment

Gonadal histology is required for diagnosis in intersex patients with abnormal gonadal development like MGD and TH, recently called ovotesticular DSD. Although sex may be assigned before the biopsy is taken, histology in these patients is required for definitive diagnosis.

Gonadal biopsies must be taken along the longitudinal axis of the gonad as both ovarian and testicular tissue may be found at the polar ends of the gonad (Figure 109.5). Patients with TH may have an ovary (O) and testicle (T); bilateral ovotestes (OT); or an O and OT.

Surgical management in DSD should also consider options that will facilitate the chances of fertility. The ovarian component of ovotestes may be separated, and the testicular tissue removed, using a zoom lens, although it must be kept in mind that these gonads need to be followed closely.

If a streak gonad is recognized like in most patients with MGD, it is removed without prior biopsy together with the surrounding peritoneum and the ipsilateral gonaduct (Figure 109.6). This gonad has to be removed, avoiding previous biopsy, as it has a 25%–50% chance to develop a gonadoblastoma and or dysgerminoma and as there is the possibility of an in situ tumor at the time of the procedure. It is usually associated with an intra-abdominal or inguinal dysgenetic testicle, which is removed at the same time in patients with female sex assignment. Although there is the same risk of malignancy in the contralateral gonad (dysgenetic testicle), it may biopsied and preserved in the scrotum of patients with male sex assignment because this gonad is functional.

The highest tumor risk is found in testis-specific protein, Y-encoded (TSPY) positive gonadal dysgenesis and partial androgen insensitivity (PAIS) with intra-abdominal gonads, whereas the lowest risk (5%) is found in ovotestis and complete androgen insensitivity (CAIS).

To analyze the spectrum of gonads of the DSD patients that we treated and assess the incidence of germ cell tumors,

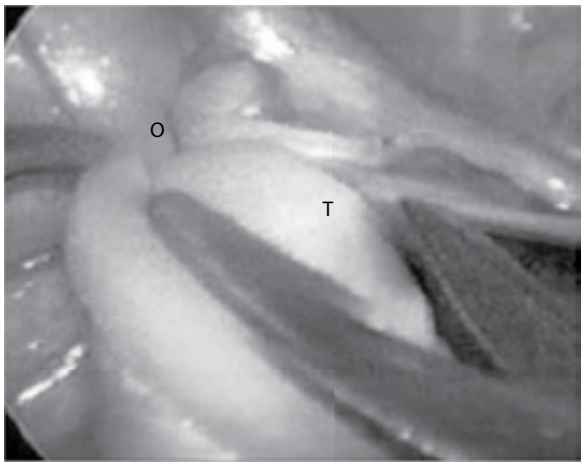

Figure 109.5 A laparoscopic view of ovotestes. This is the technique for gonadal biopsy along the longitudinal axis of the gonad. O, ovarian portion; T, testicular component.

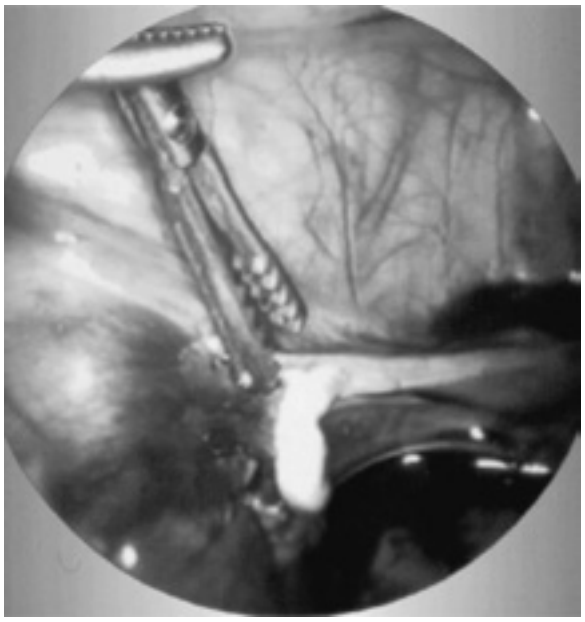

Figure 109.6 A laparoscopic view of a streak gonad. Bipolar coagulation of the gonadal pedicle. These gonads are resected en bloc with the surrounding peritoneum.

we conducted a prospective and observational study of DSD patients who underwent gonadal surgery. Age, sex assigned, scale of external masculinization (EMS), karyotype, molecular analysis, surgical approach, and pathology of the gonads were analyzed. Patients were divided into three groups: chromosomal dysgenesis (G1), 46,XX gonadal dysgenesis (G2), and 46,XY gonadal dysgenesis (G3). More than half of the gonads were intra-abdominal and were treated laparoscopically using 3 or 5 mm instruments. All streak gonads were removed, avoiding previous biopsy. We always waited for the result of biopsy before removing any gonad other than a classical streak. An inguinal approach was indicated in patients with palpable gonads. We still prefer a laparoscopic approach in most of them as it not only enables better visualization of potential Mullerian structures but also allows for treatment of a patent peritoneal sac when removing the gonads, with better cosmetic results. In total, 94 patients with a mean age of 56.42 months (range, 2–216 months) were analyzed. Forty-eight patients (19 with Turner syndrome) with a mean age of 105 months (range, 2–216 months) were included in G1. The karyotype was 45,X0/46,XY in 87.5% of them. Male sex was assigned in 19, with a mean of 7.26 EMS (range, 1–10 EMS). Histological analysis of 89 gonads was completed, identifying 52 streak gonads, 32 dysgenetic testes, and 5 ovotestes. Six germinal cell tumors (GCTs) were found in four patients. Fifteen patients with a mean age of 27.6 months (range, 2–180 months) were included in G2. Male gender was assigned to six with a mean EMS of 6.82 (range, 4–8.5 EMS). Twenty-nine gonads were analyzed: 10 ovotestes, 15 dysgenetic testes, and 4 ovaries. Bilateral gonadoblastoma was found in a 6-month-old patient with bilateral ovotestes Mean age of the 31 patients in G3 was 69.71 months (range, 5–192 months). Five of them had an SF1 NR5A mutation, six a WT1, six a CAIS, and three a PAIS. A new mutation in the SRY (p.MET64VAL) gene was identified in two sisters. Male gender was assigned in 10 with a mean EMS of 4.52 (range, 1–10 EMS). Fifty-nine gonads were analyzed, identifying 41 dysgenetic testes, 10 streak gonads, and 8 testes, Eight GCTs were found in five patients (16%, seven in streak gonads and one in a dysgenetic testis).

We concluded that DSD patients with gonadal dysgenesis have a wide variability. The incidence of gonadoblastoma is not negligible in 46,XY, and even feasible in 46,XX. The incidence of GCT was 8.3%, 6.6%, and 16% in G1, G2, and G3, respectively. Early histological analysis and monitoring of these patients is mandatory. To our knowledge, this is the first report of bilateral gonadoblastoma in ovotestes at a very early age.

Although we used to schedule simultaneous gonadal and genitalia procedures with good results encouraged by the laparoscopically better visualization and quicker intraperitoneal access, actually we prefer to avoid resection of any gonad except a classical streak before having definitive histology and to postpone genital surgical procedures.

Sex may be assigned prior to laparoscopy in patients with 45,X0/46,XY gonadal dysgenesis. This is based on a functional and psychosocial assessment in combination with the results of karyotyping, HCG testing, and interview of the parents.

We have never found functional ovarian tissue in these patients.

TH patients do not have such a classical pattern, and definitive histology is often necessary for sex assignment. Although the most common karyotype is 46,XX and the most common gonadal combination ovary/ovotestis, each case is unique and should be treated on an individual basis. Sometimes, the macroscopic aspect of the gonad and gonaduct as well as the result of a frozen section biopsy strongly favor gonadectomy in patients with previous sex assignment. There is the advantage of a laparoscopic approach in these patients requiring secondary pelvic exploration, especially because many of them are potentially fertile.

An additional role of laparoscopy is excision of Mullerian structures and prostatic utricles and orchidopexy in patients raised as males. In patients with a symptomatic utriculus, removal is best performed laparoscopically to increase the chance of preserving continuity of the vas deferens.

An inguinal approach may be indicated in patients with palpable gonads (Figure 109.7). We still prefer a laparoscopic approach in most of them as it not only enables better visualization of potential Mullerian structures but also allows for treatment of a patent peritoneal sac when removing the gonads, with better cosmetic results. In addition, most of these patients have asymmetric gonads, with one of them being intra-abdominal. We reserve the inguinal approach for XY patients with symmetric palpable gonads, introducing the telescope through the associated hernia sac in order to rule out the presence of Mullerian structures.

Figure 109.7 An inguinal approach for gonadectomy in a CAIS patient with palpable gonads.

Feminizing genitoplasty

Fortunately, there have been many advances in ambiguous genitalia reconstruction, with many surgeons contributing. Cosmetically, a near-normal appearance can now be achieved, but long-term functional results with newer techniques are still unknown.

Timing for this type of surgery is controversial. It is now our belief that one-stage total reconstruction can be done in most patients in the early months of life.

Nowadays, there is a strong influence of movements toward postponing any kind of surgery in the genitalia until the individual is able to decide and consent. There are even legal regulations in some countries.

Regardless of the timing or the procedure elected, the surgery must be done meticulously with a clear understanding of the anatomy and only be undertaken in centers with great experience and after all aspects of controversy have been explained in detail to the parents.

It consists in the following: (1) management of clitoral enlargement, (2) reconstruction of the UGS, and (3) labioplasty.

MANAGEMENT OF CLITORAL ENLARGEMENT

Management of clitoral enlargement remains controversial because of the ablative nature of the structure so vital to psychological body image and gender. Initial techniques consisted in total clitorectomy based on the belief that it was necessary to prevent gender dysphoria. However, new understanding that an intact clitoris plays a crucial role in the development of female sexuality has stimulated a more conservative surgical approach, but recession of the clitoris, keeping the corpora, may lead to painful erections during sexual arousal. The most used technique has been that based on Kogan's reduction clitoroplasty including removal of the corporal erectile tissue with preservation of the neurovascular bundle to the glans (Figure 109.8a,b,c). Glans reduction was accomplished by superficial excise of the epithelium of the glanular groove, avoiding a scar in the glans tissue, which is fixed to the pubis attachment.

There is evidence that innervation of the glans comes from the surrounding skin and plays an important role in sexual arousal, so in the last few years, we have been very careful in preserving most of it, trying to avoid its unnecessary sectioning. We also keep not only the dorsal pedicle but also the ventral skin and mucosal surface, and prefer not to excise the glans in any surface and but to hide it.

Recently, a nonablative and potentially reversible technique that dismembers the corporal bodies while keeping them in the labia major has been described in response to new understanding that an intact clitoris plays a crucial role in the development of female sexuality, but no long-term follow-up is available.

RECONSTRUCTION OF THE UGS

UGS abnormalities are a spectrum that goes from a labial fusion to an absent vagina depending on the location of the vaginal confluence in the UGS. Powell described four types: I, labial fusion; II, distal confluence; III, proximal confluence; and IV, absent vagina. In 1969, Hendren described different procedures required for reconstruction depending on the location of the vaginal confluence in the UGS related to the external sphincter (low when distal and high when proximal to the sphincter). This has been very helpful for reconstructive understanding, but the vagina is not always high or low and the sphincter not well seen. We have found a wide spectrum of vaginal location, from a normal position to an entrance in the bladder.

Low confluence was classically repaired by a *flap vaginoplasty* and mid to high by a *pull-through vaginoplasty*.

Even in the low type, we advocate for a very aggressive dissection of the posterior vaginal wall, separating it from the rectal wall. The vagina is then cut in the midline well back into its normal caliber, and at this point, a wide cutaneous flap can be sewn using delicate sutures. A rectal finger is very useful to facilitate vaginal exposure (Figure 109.9a,b). This maneuver of bringing the vagina out rather than skin in prevents the known complications of the Fortunoff flap (growing of hair and stenosis).

Exteriorization of the high vagina in the severely masculinized female is a surgical challenge. The vagina must be detached from the UGS and then connected to the perineum. The pull-through principle consists in placing a Fogarty balloon catheter into the vagina cystoscopically to locate it by palpation deep in the perineum later (Figure 109.10a,b). The UGS is approached like a bulbous urethra. Perineal anatomy in severe cases is like that in a normal male. The vagina is incised over the balloon and detached from its entry point in the UGS, and the anterior wall carefully dissected off the overlying urinary tract. The vaginal walls to reach the perineum may be constructed using a combination of inverted-U cutaneous flap (Fortunoff), preputial flap (Gonzalez), and redundant tissue from the UGS (Passerini flap).

The anterior sagittal transrectal approach in a prone position (ASTRA) is another way of exposure through the perineal approach.

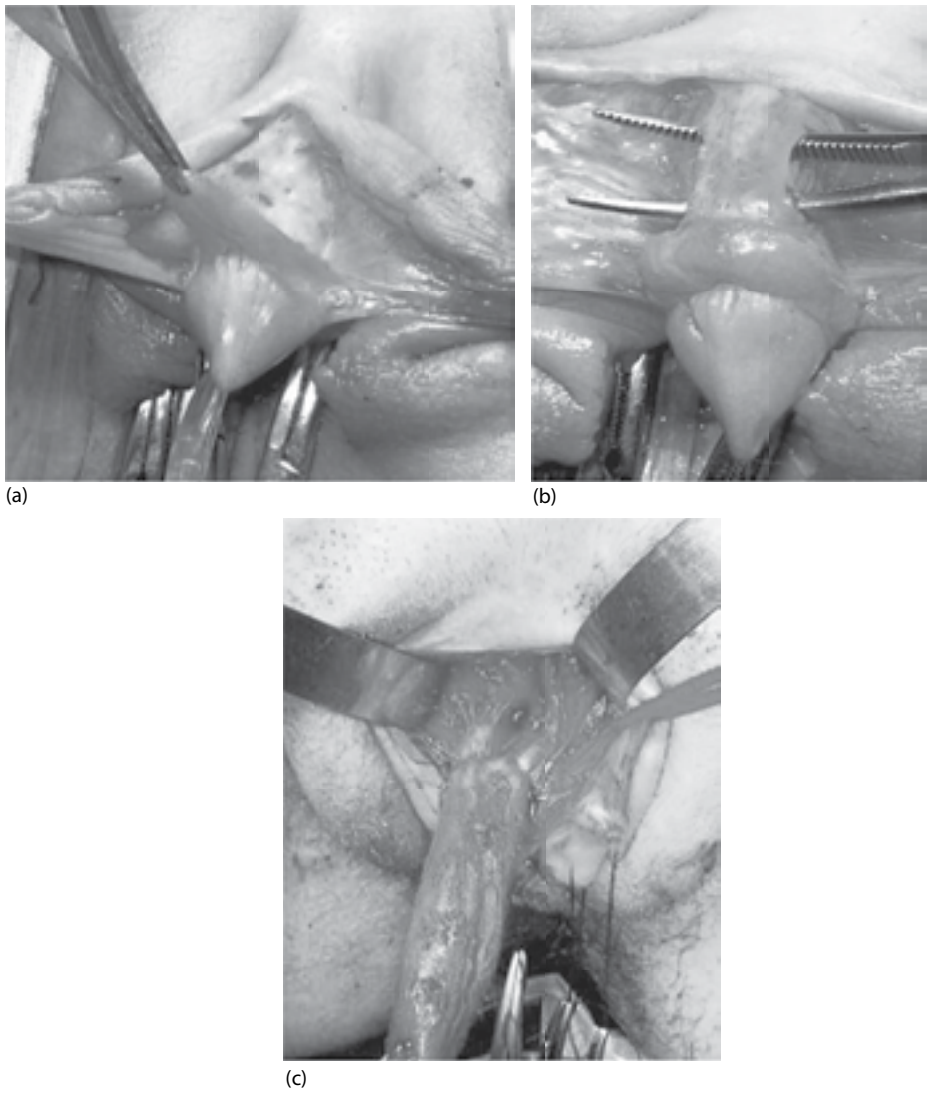

Figure 109.8 Reduction clitoridoplasty. **(a)** Dorsal incision of skin; **(b)** isolated neurovascular bundles; **(c)** corporal erectile tissue is ready to resection.

In the middle of these two points, we found what we called intermediate (IT) UGS. Although the vaginal opening is far from the UGS opening, needing an aggressive dissection to get to the vagina, there is enough proximal urethra between the bladder neck and the vaginal entrance. After Alberto Peña's (1997) description of "total urogenital mobilization" (TUM) for the treatment of cloacas, we started using this maneuver to treat intermediate UGS abnormalities. The UGS is mobilized en bloc to the perineum (Figure 109.11a,b). We used this principle but in the lithotomy position and without previous opening to prevent bleeding, and never amputate the sinus tissue until the end as it may be used to enlarge the introitus. Each patient must be individualized, and this technique can be combined with a pull-through if required, but it has simplified many of these repairs.

Richard Rink has recently described a variant that he calls partial urogenital mobilization (PUM), stopping dissection at the level of the pubourethral ligament. Currently, regardless of the level of the confluence, he starts with PUM, allowing a unified approach to all repairs.

We always started dissection in the posterior wall of the UGS with an aggressive separation from the anterior rectal wall. If the wide portion of the vagina was reached, dissection stopped, and the UGS opened ventrally, widening to the introitus. When more dissection was required, the anterior wall of the UGS was dissected and carefully freed from the low retropubic space. Then the UGS was opened either ventrally or dorsally.

In our opinion, the best way to treat the high UGS was the combination of some of these techniques. We started by placing a balloon catheter (most of the times a Foley one using a catheter as a guide) in the vagina with a cystoscope. We mobilized the UGS in the lithotomy position without opening it (Figure 109.12a). We then turned the patient to the prone position. The perineum was incised in the midline and surrounding the anterior anus. The rectum was retracted, and only in a few patients

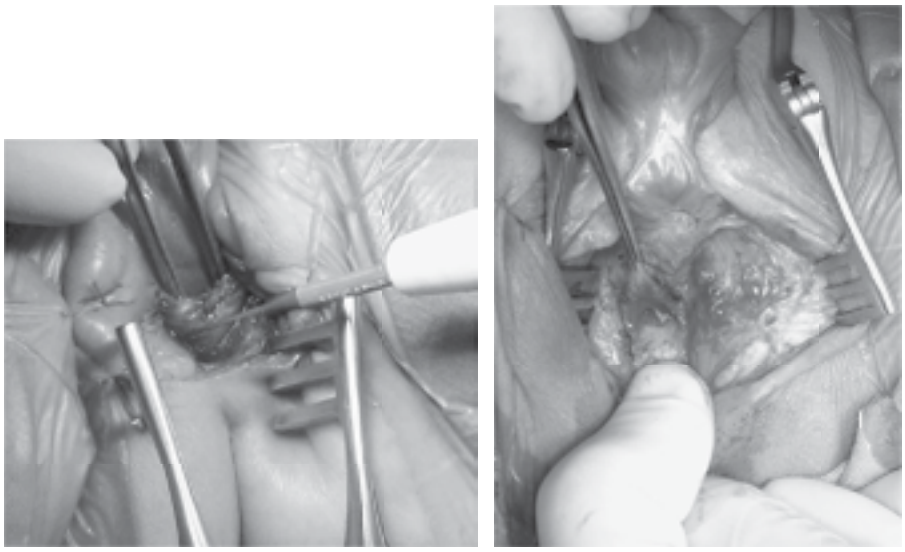

Figure 109.9 **(a)** Dissection of the posterior vaginal wall, separating it from the rectal wall before sectioning the urogenital sinus. **(b)** A rectal finger is very useful to facilitate vaginal exposure.

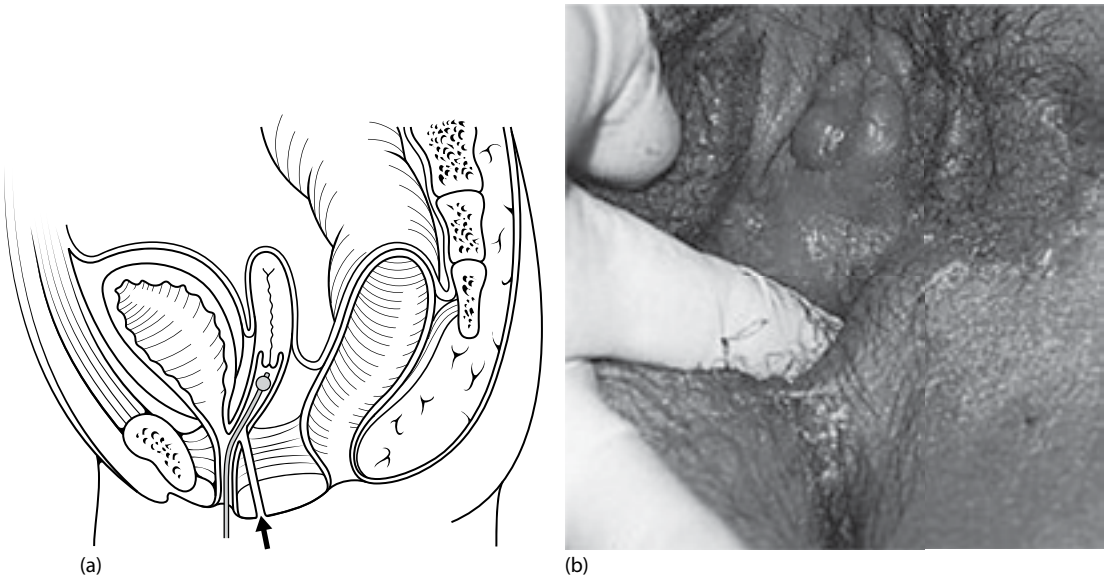

Figure 109.10 **(a)** Illustration showing the pull-through technique. The principle consists of placing a Fogarty balloon catheter into the vagina cystoscopically to locate it by palpation deep in the perineum later. **(b)** Cosmetic appearance after pull-through technique.

did the anterior wall need to be opened (Figure 109.12b). The vagina was then incised over the balloon, the Foley catheter repositioned in the proximal urethra, and the urethrovaginal fistula closed, taking care not to denervate the bladder neck (Figure 109.12c,d). The short vagina (which is usually the case in these patients) needed to be exteriorized. The transected perineal skin between the vagina and rectum was used to reconstruct the dorsal wall and the previously dissected UGS for the ventral wall. For that purpose, it was transected ventrally and everted to reach the vagina. In this way, the proximal part of it stayed as the urethra (Figure 109.13a,b,c).

So as you can see, we combined principles (pull-through, TUM, and ASTRA) rather than using a single technique. Thus, in our experience, the technique utilized to correct UGS in CAH needs to be tailored to the individual anatomy of the patient.

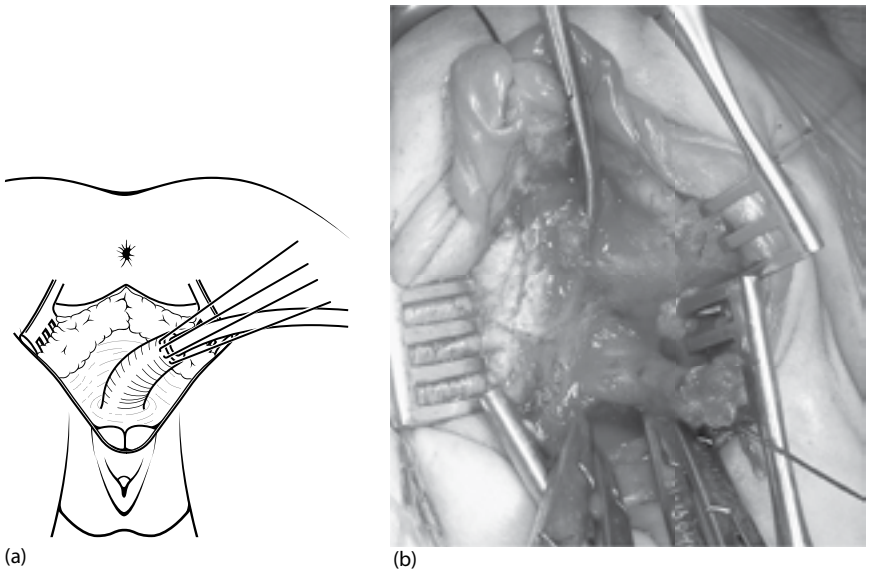

Figure 109.11 Total urogenital mobilization (TUM). The urogenital sinus is mobilized en bloc to the perineum, after it is incised in the ventral wall. **(a)** Illustration of TUM. **(b)** Operative TUM technique.

Those patients with absent vagina (type IV) should undergo vaginal replacement. Most of them are undervirilized males, and a bowel vagina (colon if possible) is preferred.

We have been doing this completely laparoscopically since 1999 (Figure 109.14).

LABIOPLASTY

Labioplasty was performed by dividing the clitoral hood skin in the midline (Byars), sewing the flaps around the clitoris and along the central mucosal strip down to the lateral vaginal walls (Figure 109.15a,b,c).

Urethral/penile reconstruction

This will be addressed in Chapter 110.

- **Postoperative:** The perineum needs to be kept dry and clean for the first week to prevent dehiscence. The urethral catheter is left depending on the technique used. We only leave it for the first postoperative day in low or intermediate UGS and for at least 3 days in high UGS.

Most of the patients only require analgesic-antipyretic and anti-inflammatory (AINES) drugs for pain treatment.

COMPLICATIONS

Techniques for vaginoplasty carry the potential for scarring at the introitus, necessitating repeated modification before sexual function.

The risks from vaginoplasty are different for high and low confluence of the urethra and vagina. The risk of urinary incontinence is decreased by recognizing the localization of the vaginal confluence for the selection of the surgical approach and avoiding unnecessary mobilization or dissection in the urethrovaginal septum.

LONG-TERM RESULTS

The pattern of surgical practice in DSD is changing with respect to the timing of surgery and the techniques used. It is essential to evaluate the effects of early versus later surgery in a holistic manner, recognizing the difficulties posed by an ever-evolving clinical practice.

Some studies suggest satisfactory outcomes from early surgery. Nevertheless, outcomes from clitoroplasty identify problems related to decreased sexual sensitivity, loss of clitoral tissue, and cosmetic issues.

Analysis of long-term outcomes is complicated by a mixture of surgical techniques.

We evaluated postoperative urinary continence in 55 patients with CAH with intermediate and high UGS who underwent a UGS mobilization maneuver. The operations we performed have not compromised urinary continence as also previously observed by others.

The outcome in undermasculinized males with a phallus depends on the degree of hypospadias and the amount of erectile tissue (Figure 109.16). Feminizing genitoplasty as opposed to masculinizing genitoplasty requires less surgery to achieve an acceptable outcome and results in fewer urologic difficulties. Long-term data regarding sexual function and quality of life among those assigned female as well as male show great variability. There are no controlled clinical trials of the efficacy of early (12 months of age) versus late (adolescence and adulthood) surgery or of the efficacy of different techniques.

Gender-role change occurs at different rates in different societies, suggesting that social factors may also be important modifiers of gender-role change.

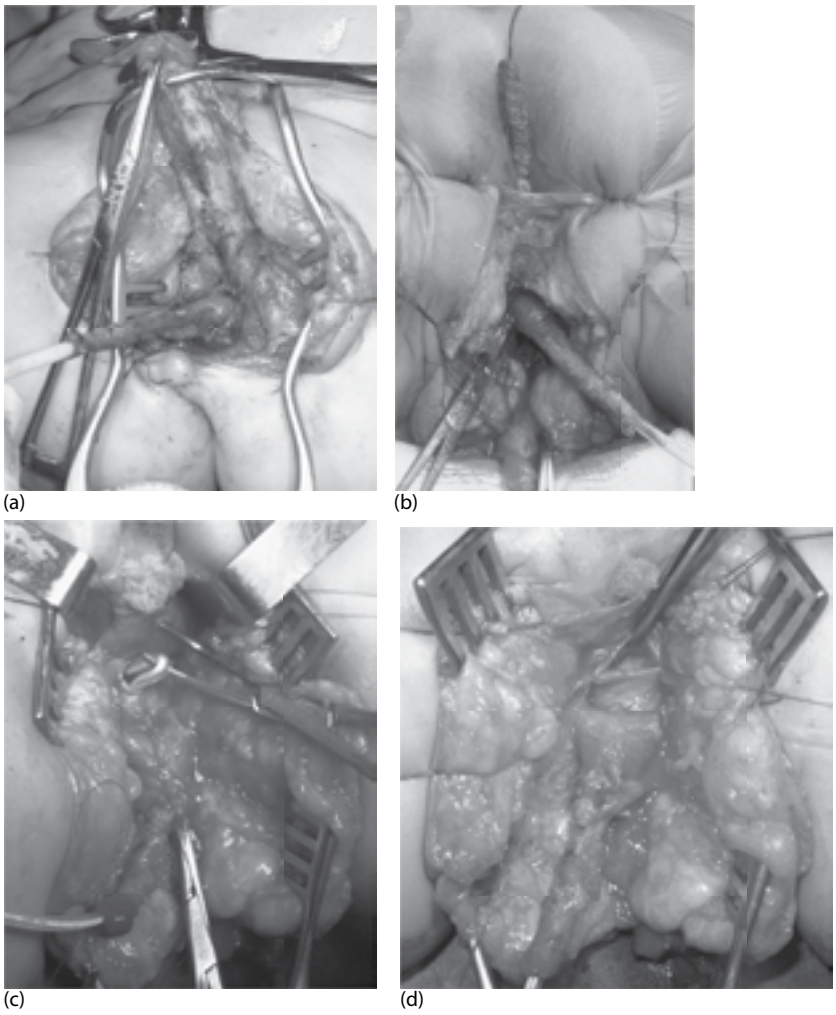

Figure 109.12 **(a)** Mobilization of the urogenital sinus in the lithotomy position without opening it. **(b)** The anterior sagittal transrectal approach. A midline sagittal incision was made through the anterior anorectal wall and provided an excellent view of the complete urethra and vagina without the need for complex preparation to gain exposure. In this patient, a previous placing of a balloon catheter in the vagina and a total urogenital mobilization were performed in the lithotomy position, and the patient was then turned to prone position. She had a very high urogenital sinus. **(c)** The vagina opened over the balloon and the Foley catheter repositioned in the proximal urethra. **(d)** The vagina is completely open.

Male genital anomalies

JOHN M. HUTSON

Development of the external genitalia is a complex process in the male, which predisposes to many congenital anomalies. Understanding these anomalies requires detailed knowledge of the embryology, and particularly the central roles of androgens (in coordinating the masculinization of the anatomy) and formation of the processus vaginalis (which allows descent of the intra-abdominal fetal testis into the scrotum).

EMBRYOLOGY

Masculinization of the external genitalia occurs in normal human embryos between 8 and 12 weeks of gestation. The endodermal urethral plate canalizes and the inner genital folds fuse to create the male anterior urethra and corpus spongiosum, while the fused outer genital folds make the scrotum. The genital tubercle enlarges to form the phallus. All these processes are mediated by testosterone from the embryonic testis. An enzyme in the target tissues, 5-alpha-reductase, converts the small amount of circulating testosterone into dihydrotestosterone, which binds 5–10 times more tightly to the androgen receptor than testosterone itself, enabling androgen to act on the androgen receptors in the external genitalia. Although the genitalia appear "male" by 12 weeks of gestation, the phallus is still tiny, but it continues to grow throughout pregnancy, in response to testosterone, to reach its newborn size (3–4 cm stretched length).

Normal testicular descent is multistaged. The first phase involves enlargement of the genitoinguinal ligament (or "gubernaculum") and regression of the cranial suspensory ligament. The swollen distal gubernaculum anchors the embryonic testis near the groin during enlargement of the abdominal cavity. The hormonal regulation of this enlargement is by Leydig insulin-like hormone3 (Insl3).[1,2]

The second phase of testicular descent involves a peritoneal diverticulum (processus vaginalis) forming inside the gubernaculum, as it migrates from the external ring to the scrotum. Gubernacular migration (with elongation of the processus) to the scrotum is likely to be controlled by the genitofemoral nerve releasing calcitonin gene-related peptide, under stimulation of androgen.[3] Until migration is complete, the distal end of the gubernaculum is not anchored to the scrotum, which could predispose to perinatal (extravaginal) torsion. After migration is complete, the gubernaculum involutes and the tunica vaginalis becomes adherent inside the scrotum, preventing any further risk of extravaginal torsion.

Following testicular descent, the proximal processus vaginalis obliterates, leaving the testis within the tunica vaginalis. Failure of closure leads to inguinal hernia, hydrocele, or encysted hydrocele of the cord. In addition, failure of the fibrous tissue around the processus to disappear completely predisposes to acquired undescended testis (the "ascending" testis) later in childhood.

PENIS

The neonatal male penis is a focus of considerable parental anxiety and attention. The foreskin in a premature infant may appear relatively deficient, but by term, it protrudes beyond the glans. The inner prepuce is adherent to the glans, and the distal opening is narrow, sometimes making catheterization difficult. Phimosis or balanitis is rare in the neonatal period, although phimosis can occur secondary to neonatal cystoscopy in babies with urethral valve.

Circumcision

Neonatal circumcision is one of the commonest operations in the United States and Israel, although in other Western countries, the frequency is much lower (Dave et al. 2003).[4–6]

The procedure was known in the ancient societies of the Middle East and may have arisen as way of preventing balanitis and phimosis in an arid, sandy region. Circumcision is part of the ritual for such religions as Judaism, Christianity, and Islam, which all arose in the same geographic area.

In our own time, there is controversy over the advantages versus the risks of routine neonatal circumcision (AAP 2012).[7,8] The American Academy of Pediatrics (AAP)

first issued guidelines about neonatal circumcision in 1971, concluding that there was no absolute medical indication for routine circumcision (AAP 2012). Then evidence showed a potential benefit of circumcision in preventing neonatal urinary tract infection and sexually transmitted diseases (STDs), including HIV, which led to a revision of the guidelines to balance the risks against the advantages (Bailey et al. 2007).[9] The current position of the AAP is to provide parents with an informed choice with accurate and unbiased information. Where circumcision is requested, the AAP now recommend that procedural analgesia be provided (AAP 2012).

Circumcision should prevent phimosis, paraphimosis, and balanitis, although good population studies proving this are hard to find. Learman[10] concluded that the evidence supporting circumcision was too weak to recommend routine operation. Urinary tract infection in neonatal males can be reduced by circumcision from 7/1000 to 1.9/1000,[11] but whether improved penile hygiene would have the same effect is unknown. STD rates in circumcised men are 10% lower than without circumcision, when comparing men presenting to an STD clinic in a Western country.[12] In sub-Saharan Africa, the benefits of circumcision in reducing HIV risk may be much greater,[13] although meta-analysis has not confirmed a benefit.[14,15] Circumcision is linked with a threefold reduction in penile cancer, although the low frequency of the condition does not justify routine neonatal operation. Learman[10] estimated that over 300,000 circumcisions were required to prevent one penile cancer/year. In Denmark, the incidence of penile cancer has fallen, despite no increase in circumcision, suggesting that other factors such as hygiene are important.[16]

The complications of circumcision may be extreme, including amputation or diathermy necrosis,[17] although most complications are minor (e.g., minor bleeding or infection) and uncommon (<1%)[18] (Figure 110.1). The Plastibell device and the Gomco clamp both have a low (0.2%) complication rate in neonates and are equally safe techniques.[10]

Neonatal circumcision should only be performed with adequate analgesia, using a ring penile block, local anesthetic cream, or a dorsal penile nerve block. If a Plastibell device is used, it is important to select the right size to avoid the ring slipping down the shaft and causing a form of paraphimosis.[19] The key to circumcision in the neonate is complete mobilization of the foreskin by separation from the glans with a lacrimal probe, and then inspection of the glans and urethral meatus to exclude hypospadias or other anomalies. Marking the level of the coronal groove through the base of the foreskin ensures that the skin of the shaft is not pulled up into the device.

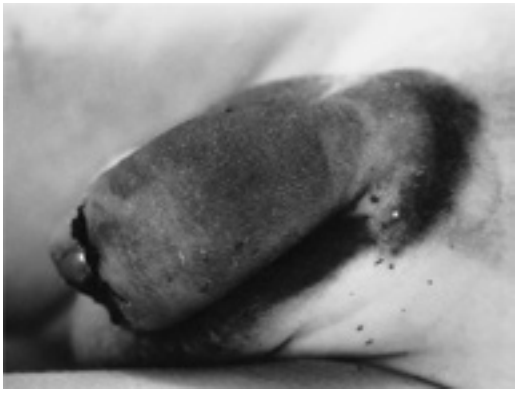

Figure 110.1 Postoperative penile hemorrhage after circumcision.

Hypospadias

Failure of canalization of the urethral plate ± failed fusion of the inner genital folds leads to hypospadias (Greek for "hole underneath"). Secondary anomalies include deficiency of the ventral prepuce (leading to a "dorsal hood") and relative deficiency in growth of the periurethral tissues compared with dorsal structures such as the corpora cavernosa. The latter causes "chordee," or relative curvature of the penis, particularly on erection.[20]

Depending on diagnostic criteria, the incidence of hypospadias is 1/100 to 1/300.[21] Siblings or the father is affected in about 10% of patients, suggesting polygenic inheritance. Hypospadias varies widely in severity, from a minor degree of meatal ectopia on the ventral glans to severe abnormality with a perineal opening.

"Hypospadias" can be confused with more serious genital anomalies, and the most important initial aim is to exclude a serious disorder of sex development (DSD) (Figure 110.2). If hypospadias is an isolated anatomical anomaly of anterior urethral development, the rest of the external (and internal) genitalia should be normal. By contrast, patients with DSD have extensive genital abnormalities secondary to failure of all aspects of androgen-dependent development. A significant DSD can be excluded if the scrotum is completely fused

Figure 110.2 Apparent "hypospadias and bifid scrotum" in a child with a severe genital anomaly. This child needs urgent investigation for DSD.

and both testes are descended. Babies with possible ambiguity need immediate referral, while those with hypospadias alone can be managed after the neonatal period.

Surgical treatment can be offered after 6 months of age, often as day surgery or overnight stay. Admission may be needed for urinary diversion, depending on severity of the anomaly and surgeon preference. A wide range of techniques are available,[22–25] which are not the main subject of this volume. Readers should consult the references for specific details.

Epispadias is a more severe and distantly related condition, which is more related to exstrophy of the bladder, which is included in Chapter 80.

Micropenis/buried penis

A small penis may be caused by inadequate hormonal stimulation during the second half of pregnancy (hypothalamic or pituitary deficiency), although in some cases, there is an anatomical deficiency. The buried penis occurs where the erectile tissue is adequate but the shaft skin is deficient.

Micropenis responds to androgen treatment, although whether postnatal hormone therapy is beneficial is controversial.[26] A number of operations have been proposed for buried penis, most of which use the foreskin.[27,28]

Penoscrotal web is a variant of buried penis where there is inadequate ventral shaft skin. This can be repaired later in infancy by Z-plasty.

Rare penile anomalies

Rare anomalies of the penis may present at birth, including urethral duplication (Figure 110.3) and megalourethra, which may be associated with prune belly syndrome.[20] Partial duplication of the caudal embryo may lead to duplication of the penis, while penile "agenesis" is usually a form of posterior ectopia, with the erectile tissue and urethra buried in the perineal body and the meatus on the anterior lip of the anal canal.[29–31] The latter anatomy is similar to the normal situation in marsupials, where the scrotum is inguinal in position and the phallus is in the perineum. Minor variants of penoscrotal transposition are common in DSD patients.[32]

Figure 110.3 Urethral duplication in an infant.

Undescended testis

Any anomaly in the anatomical structures involved in testicular descent, or their hormonal regulation, will lead to congenital maldescent. Failure of the transabdominal phase causes intra-abdominal testes that are truly "cryptorchid" or hidden. Impalpable testes within the abdomen or canal are relatively uncommon (<5%–10% of patients, depending on different authors[33]).

Intra-abdominal testes are associated with hypoplasia of the ipsilateral scrotum and often with absence of the external inguinal ring. The latter is a useful clinical feature to confirm absence of any inguinoscrotal migration. When the testis is inside the canal, the external ring may be open, consistent with intermittent emergence of the canalicular gonad.

The common site for undescended testes is just outside the external ring, in the "superficial pouch," which is the name given to the tunica vaginalis when it is in the groin, superficial to the abdominal wall and deep to the superficial fascia (Scarpa).[34]

Maldescent is likely to have multiple causes, the commonest being failure of gubernacular migration for various mechanical reasons.[35] Transient deficiency of gonadal androgens related to hypothalamic or pituitary anomalies or defects in placental function also may be important.[36] A number of less common and rare causes for cryptorchidism have been proposed (Table 110.1 and Figure 110.4).

In premature infants as well as many term babies, cryptorchidism may be transitory, with further descent into the scrotum in the first 12 weeks postnatally (John Radcliffe Cryptorchidism Study Group 1992).[37] These so-called "late descenders" are at a high risk of developing acquired "ascending" testes later in childhood. The etiology of the latter is controversial, but has been proposed to be failure of the processus vaginalis to obliterate fully postnatally, leaving a fibrous remnant that prevents the normal elongation of the spermatic cord with growth.[3]

DIAGNOSIS

The aim of the physical examination is to locate the testis and determine its lowest position without undue tension. The latter corresponds with the caudal limit of the undescended tunica vaginalis.[38] In neonates, the examination may be hampered by vigorous leg movements, small size of all structures (including the testis, which is only 1–2 mL in

Table 110.1 Proposed causes of cryptorchidism in rare cases

1. Aberrant location of genitofemoral nerve (perineal testis)
2. Persistent Mullerian duct syndrome (transverse ectopia with uterus and elongated gubernaculum)
3. Prune belly syndrome (massive bladder enlargement precluding entrance into inguinal canal)
4. Posterior urethral valves (segmental mesenchymal defect)
5. Anterior abdominal wall defects (ruptured gubernaculum)
6. Connective tissue disorders (deficient gubernacular migration)
7. Neural tube defects (genitofemoral nerve anomalies)

Figure 110.4 Ectopic undescended testis. In this case of perineal testis, it has been suggested that the cause is aberrant migration of the gubernaculum secondary to abnormal location of the genitofemoral nerve.

volume), and motility of the testis within the tunica vaginalis. The scrotum is hypoplastic if the testis has never reached it, and the inguinal canal is closed in intra-abdominal testes. Palpation of a triangular defect at the pubic tubercle confirms that the external ring is open and suggests that the testis is inside the canal. Conversely, hypertrophy of the contralateral testis (2–3 mL) suggests atrophy of the ipsilateral organ ("the vanishing testis").

TREATMENT

Surgical treatment of undescended testis aims to relocate the gonad into the scrotum before secondary dysfunction and degeneration occur (from high temperature). It is based on a premise, currently not proven in humans, that early placement of the testis in the scrotum will allow normal postnatal maturation of the germ cells to proceed. Careful study of testicular biopsies now suggests that the germ cells undergo transformation, from gonocytes to type A spermatogonia, within 6–12 months after birth,[3] and that this maturation is deficient or arrested in cryptorchid testes. In addition, adult dark spermatogonia are now thought to be the stem cells for subsequent spermatogenesis.

The recommended age of orchidopexy has changed over the years, reflecting accumulating knowledge about testicular function in infants. There is a current consensus that orchidopexy should be done about 6–9 months, as long as anesthetic support is adequate. Since 4%–5% of the males have undescended testes at birth, but about half of these show postnatal descent by 12 weeks, the baby should be reexamined then to confirm persisting cryptorchidism prior to referral for surgery. At this age, the operation is best performed by a trained pediatric surgeon, familiar with the handling of delicate tissues. Recent prospective trials confirm that surgery at 9 months leads to better testicular growth (measured by ultrasonography) than when operation is delayed until 3 years of age.[39]

Rare anomalies of the testis

Tumors of the testis are rare at birth, but teratomas have been reported (Figure 110.5). In a review of 68 patients with testicular tumors over 30 years, we found one newborn with a genital anomaly and a gonadoblastoma.[40] A neonatal teratoma may need to be distinguished from a hydrocele or testicular torsion. If the hydrocele is too tense to palpate a normal testis, an ultrasound examination would be useful. Most teratomas can be shelled out of the testis, thereby avoiding orchidectomy.

Exstrophy of the testis has been reported, presumably secondary to pressure necrosis of the scrotal skin from the baby's heel, and prolapse of the scrotal contents.[41] A similar defect may occur in the proximal penile urethra from probable pressure atrophy, leading to a congenital urethral fistula[42] (Figure 110.6).

Duplication of the gonadal primordium can cause polyorchidism. The presentation is of three scrotal masses, all of which feel like normal testis.[43] The differential diagnosis includes complete inguinoscrotal hernia, encysted hydrocele of the cord, and transverse testicular ectopia, where both testes are on the same side. In the latter situation, the contralateral hemiscrotum is empty. No treatment may be required, although one gonad can be removed if the vas deferens is deficient.

Transverse testicular ectopia is a rare anomaly, sometimes associated with prenatal rupture of the ipsilateral gubernaculum, allowing the testis to prolapse into the contralateral processus vaginalis. In most cases, the ectopic testis has no gubernacular attachments; the diagnosis can be confirmed on scrotal ultrasound.[44] Transverse ectopia of the testis is seen also in a rare form of DSD known as persistent Mullerian duct syndrome.[45] Transverse ectopia is treated by trans-septal scrotal orchidopexy (i.e., both testes

Figure 110.5 Neonate with a teratoma of the left testis.

are brought through the same inguinal canal into the scrotum, and one is placed in the contralateral hemiscrotum).

The vas deferens may be absent in the Mayer–Rokitansky–Kuster–Hauser (MRKH) syndrome type II (OMIM 601076) or in infants with cystic fibrosis. In the Rokitansky anomaly, caudal growth of the distal Wolffian duct is arrested, leading to subsequent absence of the ipsilateral vas deferens, seminal vesicle, and ureteric bud (and hence ipsilateral renal agenesis).[46] The etiology of absent vas deferens is different in cystic fibrosis, where the Wolffian ducts undergo involution/atresia in midgestation. At birth, only the head of the epididymis is palpable, and the epididymal tail and vas deferens are absent bilaterally: this finding can be used to diagnose cystic fibrosis in neonates with possible meconium ileus.[47]

Apart from DSD anomalies with separate labioscrotal folds or bifid scrotum, scrotal anomalies are rare. There are case reports of ectopic hemiscrotum and duplication, which are a local manifestation of partial twinning of the caudal embryo or compression of the perineum by the feet of the fetus.[20,48,49]

Neonatal testicular torsion

DAVID M. BURGE AND JONATHAN DURELL

INTRODUCTION

Torsion of the neonatal testis is a well-recognized clinical entity, which accounts for about 10% of all cases of testicular torsion admitted to pediatric surgical centers.[1] A UK study estimated the incidence of neonatal testicular torsion to be 6.1 per 100,000.[2] Torsion usually occurs extravaginally, i.e., in the spermatic cord above the insertion of the tunica vaginalis (Figure 111.1), but both intravaginal and mesorchial torsion are reported.[3,4] Either testis may be involved. Bilateral torsion occurs and may be synchronous or metachronous.[5,6] Asynchronous torsion may occur in as many as 33% of cases.[7]Apparent primary infarction of the neonatal testis in the absence of torsion occurs less commonly,[8] and while it has been postulated that this represents previous torsion that has untwisted, good evidence exists to suggest that the initial event in neonatal torsion is a vascular one and that torsion may occur secondarily.[3] The neonatal testis may be prone to extravaginal torsion because of its extreme mobility within the scrotum.[9]

CLINICAL FEATURES

Neonatal torsion appears to be a condition of large term babies,[3] and it rarely, if ever, affects the preterm infant. Previously, breech delivery was suspected as being a causative factor. Recent reports, however, fail to confirm this.[3] Affected babies are usually totally asymptomatic. The typical physical features are of a hard, edematous hemiscrotum with a noticeable blue or black discoloration.

The testis feels firmly adherent to the scrotal wall and is apparently nontender. While there may be some enlargement of the hemiscrotum, this is not usually marked. These features are usually present from birth, supporting the contention that neonatal torsion is often an antenatal event. However, the clinical features are not always noted at delivery and in many cases are not detected until the second or third day of age. Occasionally, features consistent with acute torsion (sudden onset of swelling, erythema, and pain) may develop some days or weeks after delivery, and it appears that in these cases, the torsion is more likely to be intravaginal. Torsion of an undescended testis may present in this way.[3]

Diagnosis can usually be made on the clinical features alone. The differential diagnosis includes hydrocele, testicular tumor, trauma, adrenal hemorrhage, and meconium peritonitis with tracking down a patent processus. Distinction from a simple hydrocele is usually easy by transillumination. Testicular neoplasia can be excluded by the presence of bluish discoloration and scrotal edema. Torsion can only be differentiated from spontaneous infarction at surgery. Some bruising of the scrotum may occur after breech delivery,[10] but this is usually in the presence of a testis that feels normal to palpation. Intraperitoneal injury from birth trauma may result in hematocele formation, but the fluctuation of this lesion will usually distinguish it from torsion. Adrenal hemorrhage may present with features indistinguishable for torsion, but adrenal ultrasound would be diagnostic.[11] While color Doppler studies of testicular artery flow and radionuclide scanning of the scrotum might support the diagnosis, they are not required.

A clinical diagnosis of neonatal torsion is sufficient indication for scrotal exploration. While it might seem mandatory that this be conducted urgently, reports of successful testicular salvage are rare.[4,12–14] The classical clinical features seem to be due to the presence of established testicular infarction, and it can be argued that the only reason for surgery is to fix the contralateral testis. Because delayed torsion of the contralateral testis does occur and may be at the extravaginal, intravaginal, or mesorchial level, early surgery to assess the affected testis, excise it if necessary, and securely fix the contralateral testis is recommended. No specific preoperative preparation is required.

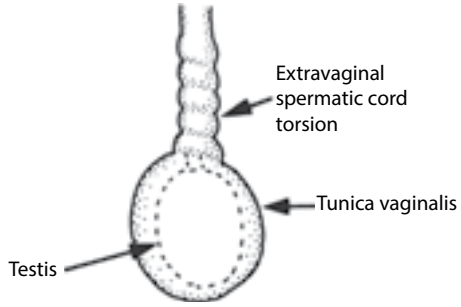

Figure 111.1 Anatomy of extravaginal torsion.

OPERATIVE TECHNIQUE

Under general anesthesia, the scrotum is incised in the midline and dissection continued into the affected hemiscrotum (Figure 111.2). Both testes are easily approached through this single incision (Figure 111.3). In most cases, established infarction will have resulted in edema and fixation of the testis to the subcutaneous tissues. It is usual, however, to find a plane of cleavage outside the tunica vaginalis, resulting in a clear demonstration of the site of torsion. In some instances, necrosis is well established, and the exact origin of the pathology cannot be identified. If, as is usually the case, the testis is clearly beyond salvage, it is wise to excise it, having transfixed the spermatic cord above the site of torsion. Retention of a necrotic testis is inadvisable as it invites sepsis, which may put the contralateral testis at risk. While there is a theoretical possibility that retention of the infarcted testis may result in some hormonal production,[9] in the majority of cases in which the affected testis is not removed, involution occurs.[3] Following excision of the affected testis, the contralateral testis is exposed through the same excision. The tunica vaginalis is opened to allow accurate inspection of the anatomy and permit effective fixation. This may be performed by placement of the testis in a subdartos pouch, as used in orchidopexy, or by suture fixation, which is now described. The tunica vaginalis is sutured to the tunica albuginea of the testis at four points, using a fine nonabsorbable monofilament material, as

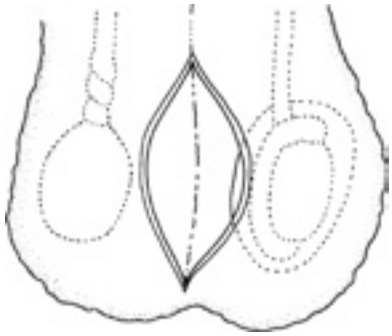

Figure 111.2 Midline scrotal incision.

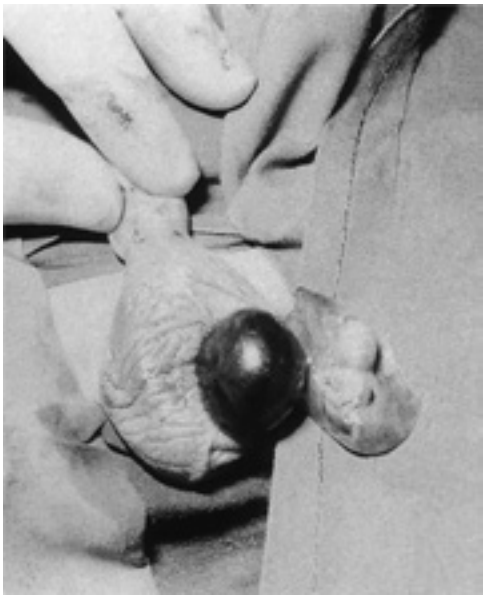

Figure 111.3 Midline exploration showing extravaginal torsion of right testis and normal left testis prior to fixation.

using an absorbable suture has been shown to have a higher rate of retorsion (88% of retorsions in the literature review used absorbable sutures),[15] thus preventing intravaginal torsion. It is wise to incorporate the scrotal septum in the two medial sutures, thus fixing the tunica vaginalis to the scrotum and preventing extravaginal torsion (Figure 111.4). Care should be taken to site these two sutures fairly deep in the wound, or else the testis will lie too superficially and skin closure will be made more difficult. The scrotal incision is then closed with a fine continuous absorbable suture. No specific postoperative care is required.

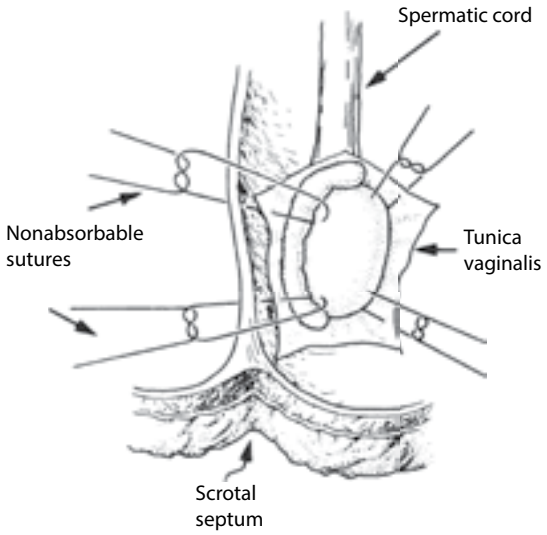

Figure 111.4 Technique of testicular fixation.

Long-term outcomes in newborn surgery

CHRISTIAN TOMUSCHAT, KEITH T. OLDHAM, AND CASEY M. CALKINS

INTRODUCTION

Ongoing advancements in the pre- and postoperative care of the neonate with a surgical condition have enabled the survival of an increasing number of infants with congenital malformations. For decades, surgeons have insisted on a regular self-examination of outcomes to ensure the optimal treatment of our patients. Outcome analysis traditionally relates to the rudimentary end result of an operation—utilizing variables such as mortality, operative time, specific complication rates (i.e., incidence of esophageal stricture following esophageal atresia [EA] repair), and hospital length of stay, to name a few. Recently, outcomes research has become a more complex endeavor. Measures of long-term outcomes, including "functional outcome" and "health-related quality of life," are equally important to the morbidity sustained as a result of a congenital malformation and its attendant surgical correction. The methods by which subjective assessments are expressed as a quantitative measure are therefore important for the newborn surgeon to understand. These data serve as an important adjunct to prenatal counseling, offer information about future health expectations for families, assist the surgeon in identifying potential improvements in perioperative management, and will likely be utilized by public agencies charged with implementing health policy, especially in an era of diminishing resources. Therefore, long-term outcomes are of specific import to the neonates we care for, the families we answer to, and our colleagues charged with the continued efforts to improve the surgical care of our youngest patients. This chapter will begin by focusing on the specific language and methodology of modern long-term outcomes research as a prelude to the current status of long-term outcomes assessment in newborn surgical conditions commonly treated by the pediatric surgeon.

WHAT IS AN "OUTCOME"?

In 1934, Ernest A. Codman, an orthopedic surgeon, espoused the "end result idea." In his book *The Shoulder*, Dr. Codman introduced this "common sense notion that every hospital should follow every patient it treats long enough to determine whether or not the treatment has been successful, and to inquire 'if not, why not?'."[1] Today, this "end result idea" represents the very basis for conducting outcomes research, which examines how interventions delivered in the treatment of medical and surgical disease affect patient populations over time. It is one of many areas of investigation within the broad field of Health Services Research.[2] Although one can formally define a "health service,"[3] it seems intuitive to say that it is any organized effort to improve the health of a patient. The measurements and assessments utilized in outcomes research have changed considerably over the course of the last two decades. Regular assessment of our operative outcomes in the form of "morbidity and mortality" conferences is and continues to be an essential endeavor to ensure that we continue to improve the surgical care delivered to infants and children. It is an indispensable form of self-assessment and allows us to learn from one of the realities of human nature—error. However, assessment of individual and system failure represents only one part of how we improve the practice of pediatric surgery. Individual quality improvement depends on refining surgical technique, learning at regional and national society meetings, remaining knowledgeable by reading relevant peer-reviewed literature, and incorporating successful strategies and techniques into practice.

Assessment of patient outcomes (bad and good) helps us to understand what works and what doesn't. In this sense, an outcome can be any measure that affects the health, perceived health, physiologic function, financial status, or experience of a patient. Modern outcome measures have developed as a result of three general trends. First, traditional clinical outcomes are supplemented by measurements that take patient experience and concerns into account, especially regarding chronic illness, where the intent is typically to treat or offer palliation, rather than provide a definitive cure. Second, when making decisions regarding healthcare, patient preference is essential, and information

on healthcare quality of life (QoL) or functional results of one treatment versus another may ultimately influence decision-making in this regard. Finally, healthcare policymakers remain under pressure to effectively allocate resources. Benefits and QoL perceived by patients and society as a whole may allow appropriate governmental bodies to do so with a sense of what is best for the collective good when resources may be limited. A common feature of health-related outcome measures today is the measurement of well-being from the subjective viewpoint of the individual patient (or parent—the "proxy") concerned. The three items crucial to an understanding of modern-day outcomes research are health-related quality of life (HRQoL), functional outcome, and utility (cost-effectiveness).

HEALTH-RELATED QUALITY OF LIFE

Where health and QoL clearly intersect—the concept of HRQoL assessment is born. In contrast to objective data obtained by laboratory, radiographic, or purely functional assessments, the measurement of HRQoL provides additional information about the subjective impact of a condition, or, for our purposes, the ramifications of an operation utilized to treat that condition. Transformation of qualitative assessments into quantitative data requires identification of measurable elements related to an individual's existence and assessment by way of an instrument.[4] Five general concepts define the scope of such an instrument: (1) impairment, (2) functional state, (3) health perception, (4) social opportunity, and (5) duration of life.[5] Distinct domains have been subsequently operationalized to translate these five concepts into quantifiable data. Although there is no consensus regarding a universal and inclusive set of domains, most researchers will agree that "quality of life" differs greatly from person to person. A survey respondent may weigh various domains differently, and one must decide how to assess for these differences when interpreting the results from a cohort of respondents. The seven general domains of health in most HRQoL surveys include physical functioning, social functioning, emotional functioning, cognitive functioning, pain/discomfort, vitality, and overall well-being.

Instrument standards

A HRQoL instrument is developed utilizing psychometric testing principles and, once constructed, is reviewed against standards outlined by the Scientific Advisory Committee of the Medical Outcomes Trust.[6] Evaluation criteria include appropriateness, validity, reliability, responsiveness, precision, interpretability, acceptability, and feasibility. Appropriateness is the first and most fundamental criterion to assess and asks whether the instrument measures what have been identified as the most important outcome(s) for the purposes of evaluation. Specifically, is the instrument relevant, and are the methods of evaluation and administration appropriate? Validity concerns whether an instrument measures what is intended. Face and content validity are matters of qualitative judgment—for instance, were the patient types targeted for assessment included in the creation of the instruments' content? Construct validation refers to comparisons with other instruments, relating the scores to sociodemographic variables and comparing domain scores within the instrument itself. Reliability assesses whether or not an instrument is consistent in its measurements—both internally and over time. Responsiveness refers to the ability of an instrument to measure significant changes in health and is assessed by looking at changes in instrument scores for groups whose health is known to have changed. The precision of an instrument is measured by the range of response options and the existence of ceiling (maximum score) or floor (minimum score) effects. An instrument is likely to be acceptable to a patient or population group if it measures what they consider being important aspects of QoL. The optimal instrument is interpretable—and is able to translate a quantitative score into an external measure that has a familiar meaning. This aspect of an instrument is easily assessed when there are normative data from a representative sample of the general populous and/or patients with similar conditions for whom the instrument is intended. Finally, feasibility refers to the time and effort needed to complete the instrument, and whether such issues are prohibitive to completion of the instrument, or affect the manner in which it is completed. The United States Centers for Disease Control has established a comprehensive website that may aid the clinician when faced with the possibility of instrument evaluation or utilization (http://www.cdc.gov/hrqol/).

Unique issues in health services research for the newborn population

As the goal of adult functioning is to be self-sufficient and economically productive, adult-based measures of functioning and QoL are not likely relevant to children.[7] Furthermore, children often view health and illness as separate entities, whereas adults see these two items as part of a continuum.[8] Lack of a consensus on a theoretical framework as to the nature of HRQoL in children means that there is lack of agreement regarding the optimal domains in a pediatric HRQoL assessment tool. Even within domains, there are often variations of emphasis. For example, within the physical functioning domain, an instrument may place varied emphasis on physical symptoms, self-care, participation in physical activities, or distress caused by limitations. As a result, different instruments may yield different results depending on the age of the child, the medical or surgical condition, the emphasis of the questions within a domain, and a variety of other factors unique to pediatric healthcare.

Although adult HRQoL measures suffer from some of the same issues of validity, the common feature of most adult instruments is that they measure health from the subjective viewpoint of the individual concerned. In children, this information is not always easily obtained from the subject. Although many children are able to provide self-reports of

HRQoL if an instrument is chosen that is appropriate to his/her abilities, this assertion has not been well evaluated. Furthermore, different domains within an instrument may pose unique challenges to different age groups. Children as young as 5 years old may be able to provide accurate self-reports of pain, whereas subjective concepts such as behavior or self-esteem may not be able to be accurately assessed until 10 years of age.[9] Several self-reporting biases are also more problematic in pediatric populations. Position bias (tendency to select the first answer), acquiescent response bias (tendency to agree with questions regardless of content), failure to accurately perceive time periods, boredom with having to answer written questions, and difficulty in understanding negatively worded items make construction of pediatric outcome tools difficult. Given that self-reports suffer from such bias and many children are truly unable to fill out a self-assessment, other individuals—"proxies"—have served to provide data on the child's behalf. Parents or caregivers who have a longstanding relationship with the patient commonly complete such proxy reports. However, the choice of proxy may add further bias to the instrument. For example, fathers rate children as having fewer behavioral and psychological problems than do their mothers.[10] In another study, children aged 8–11 years with a chronic health condition reported significantly lower HRQoL than their parent proxies.[11] In one review, nearly 90% of pediatric HRQoL assessments were completed by a proxy.[12] However, most modern pediatric-specific instruments can be utilized in a self-reporting mode, and proxy assessments may apply to only the youngest of children. When possible, self-reports should always be sought over proxy-generated data.

As the development of a child is not always linear, how does one separate development from the outcome? This is one of the several questions that remain unanswered regarding the instruments currently utilized for pediatric HRQoL. Outcome measures that not only are sensitive to changes in development and health but also make allowances for different cognitive abilities of children at various ages with regard to reporting and valuing health status are required.[13] When selecting an instrument, the clinician should consider whether the concepts inherent in the tool are developmentally appropriate for age, gender, and culture. In addition, if one is interested in measuring longitudinal HRQoL in a patient cohort, selection of an instrument with items that are not overly age-related may be optimal so that children of different ages may complete the same instrument.

To get around the problematic issue of "child-friendly" tools and feasibility, some instruments have employed unique methods to entice children to complete the surveys. For example, the KINDLR instrument employs a computerized program to measure pediatric HRQoL by means of a touch-screen monitor or a mouse. It is a child-friendly (independent of reading and writing skills, in a playful format), economical, and developmentally appropriate program that is valid, reliable, and available in two languages (German and English). Other methods to entice and facilitate child participation include third-party interviewing and age-appropriate storybook formats.

Multidimensional generic measures of HRQoL

Generic quality-of-life measures are designed to assess physical, psychological, and social aspects of health without attention to a specific ailment or disability. These instruments emphasize breadth over specificity by focusing on the common elements of health that transcend all diseases. In practice, these instruments may also augment subjective and objective clinical data that focus on signs, symptoms, and effects of a specific disease.[14] The list of instruments in Table 112.1 is not, by any means, comprehensive, but serves to highlight the most common instruments available for the assessment of generic HRQoL in infants and children.

Table 112.1 HRQoL instruments

Instrument	Applicable age	Time to complete
PedsQL™	5–18 years (self) 2–18 (proxy)	<5 minutes (self or proxy)
CHIP	"CE" 6–11 years (proxy) "AE" 6–18 years (self)	20 minutes (self or proxy)
CHQ	10–18 years (self) 5–15 years (proxy)	15–30 minutes (self) 7–30 minutes (proxy)
KINDLR	4–16 years (self) 4–16 years (proxy)	10–15 minutes (self) 10 minutes (parent)
KIDSCREEN	8–18 years (self) 8–18 years (proxy)	20 minutes (52 items) 15 minutes (27 items) 5 minutes (10 items)
DISABKIDS	4–7 years (self or proxy) 8–16 (self or proxy)	20 minutes (37 items)

Note: PedsQL: Pediatric Quality of Life Inventory; CHIP: Child Health and Illness Profile; CHQ: Child Health Questionnaire.

PEDIATRIC QUALITY OF LIFE

The Pediatric Quality of Life (PedsQL™) measurement model is a modular approach to measuring HRQoL in children and adolescents who are healthy and those with acute and chronic health conditions. The model has the added ability to integrate both generic core scales and disease-specific modules into one measurement system. The PedsQL™ generic core scales include brief (23 items), practical (less than 4 minutes to complete), and flexible (designed for use with the community, school, and clinical pediatric populations). Its permutations are meant to be developmentally appropriate (different modules for ages—child self-report ages 5–7, 8–12, 13–18; parent proxy-report ages 2–4, 5–7, 8–12, 13–18). It is one of the most interpretable tools due to its widespread use. Additionally, it is translated into multiple languages including Spanish.[15] The 23-item PedsQL™ generic core scales were designed to measure the principal dimensions of health as delineated by the World Health Organization, as well as role (school) functioning. PedsQL™ condition-specific modules complement the generic core scales and are used in designated clinical populations. These are designed to provide greater measurement sensitivity for circumscribed populations (currently available for asthma, rheumatology, diabetes, cancer, and cardiac conditions, with additional modules in the development and planning stages). For the pediatric surgeon, the PedsQL™ is an attractive option as it is brief, practical, developmentally appropriate, multidimensional, reliable, valid, and responsive. It has been cited in numerous peer-reviewed publications. The instrument can measure HRQoL over time with instruments that are age appropriate and available in both patient and proxy forms.

CHILD HEALTH AND ILLNESS PROFILE

The Child Health and Illness Profile (CHIP) instruments were developed by Dr. Starfield et al.[16] at the Johns Hopkins School of Public Health. Development of the child and adolescent editions occurred over 12 years and involved more than 5000 children and adolescents from ethnically and socioeconomically diverse families. The CHIP-CE (CE = child evaluation) instruments provide a comprehensive assessment of health status that can be completed by children 6–11 years old or by their parents. It describes aspects of health that can be influenced by health systems, school health systems, and health promotion efforts. The CHIP-AE (AE = adolescent evaluation) was developed to document the state of health in adolescent age populations, identify differences in the health of subpopulations, and assess the impact of medical and surgical interventions on health.

CHILD HEALTH QUESTIONNAIRE™

Perhaps the most commonly used outcome assessment tool in contemporary health services research is the SF-36® ("short-form 36").[17] The Child Health Questionnaire (CHQ) is a by-product of the SF-36® and a more appropriate choice for use in children and adolescents. A product of the RAND-sponsored Medical Outcomes Study (MOS), the SF-36® is a 36-item general health status assessment questionnaire. It has nine separate scales, though recent work has identified two dimensions that underlie the nine subscales: physical and mental health. There are substantial reliability and validity data for the SF-36® in a wide variety of adult populations.[18] However, the 28- and 50-item CHQ short forms (which cover the same 12 concepts as the full-length CHQ) are more efficient measures than the SF-36® and are valid for use in children aged 5–18 years.[19] In the United States, normative values and benchmarks for the parent-reported versions of the CHQ are available for some specific health conditions. The youth self-report version is 87 items and was developed for use in individuals aged 10 years and older. Authorized translations and Internet-administered versions are also available.[20]

KINDLR

Initially developed in Germany, the KINDLR is a 24-item, methodologically suitable, psychometrically sound, and flexible instrument. The questionnaire can be completed by children and adolescents (aged 4–16) or by way of a parent proxy. The questionnaire is available for different age groups. The computer-assisted version (CAT-SCREEN) is a unique method of instrument administration that may be especially suitable for toddlers. Disease-specific modules exist for obesity, asthma, atopic dermatitis, cancer, and diabetes. The KINDLR has been validated and is especially effective in the assessment of psychological well-being, social relationships, physical function, and everyday life activities.[21]

KIDSCREEN

The KIDSCREEN questionnaires are a family of instruments developed and normalized for surveying HRQoL in children and adolescents aged 8–18. The questionnaires were developed simultaneously in 13 European countries with particular regard to childhood concepts of health and well-being. Three versions of the KIDSCREEN questionnaire are targeted at children, adolescents, and parents. They are available in various languages and can be applied to multiple research goals. KIDSCREEN-52 (long version) covers 10 HRQoL dimensions, KIDSCREEN-27 (short version) covers 5 HRQoL dimensions, while the KIDSCREEN-10 Index encompasses a global HRQoL measurement. In this fashion, the questionnaires measure the QoL from the child's point of view with regard to physical, mental, and social well-being (http://www.kidscreen.org).[22,23]

OTHER PEDIATRIC GENERIC INSTRUMENTS

The Infant Toddler Quality of Life Questionnaire™ (ITQOL) was developed for use in infants and toddlers from at least 2 months of age up to 5 years. The ITQOL adopts the World Health Organization's definition of health, as a state of complete physical, mental, and social well-being and not merely the absence of disease. The survey was developed following a thorough review of the infant health literature and a review of developmental guidelines used by pediatricians. The child equivalent is the aforementioned CHQ. The

Dartmouth COOP child-report charts were developed as a survey to evaluate treatment outcomes and as a tool for the detection of important health problems. It consists of six charts addressing physical fitness, emotional feelings, schoolwork, social support, family communications, and health habits.[24] The instrument was developed by a literature review and a focus group of physicians and adolescents. The tool is completed by self and is reasonably feasible in that it contains only six items. The Exeter QoL (Exqol) measure is another generic self-report HRQoL measure for children aged 6–12 years based on the authors' experience with chronically ill children. Like the KINDL CAT-SCREEN, it is computer-administered and consists of 12 gender-specific pictures—each of which is rated twice: the first in terms of "like me" and the second in terms of "as I would like to be."

Also, significant HRQoL differences exist between parents caring for children with congenital anomalies and the general population. It would be useful to improve further our understanding of the HRQoL impact of informal caregiving, separating "caregiving effects" from "family effects" and distinguishing parent–child relationships from other caregiving situations. Poley et al.[25] underline the importance of considering caregivers, also in the context of economic evaluations. It indicates that general HRQoL measures, as used in patients, may be able to detect HRQoL effects in caregivers, which facilitates the incorporation in common economic evaluations of HRQoL effects in carers. Analysts and policymakers should be aware that if HRQoL improvement is an important aim, they should register HRQoL changes not only in patients but also in their caregivers.[25]

CONDITION-SPECIFIC MEASURES OF HRQOL

Condition-specific measures aim to assess the QoL following a specific intervention or for individuals with a specific diagnosis. When condition-specific instruments are developed to assess the QoL following treatment of a specific anomaly, such measures are designed to be more sensitive to the detection of small treatment effects when compared to generic measures. In this regard, a condition-specific measure is designed to tap the domain(s) of greatest interest for the condition in question. A variety of studies have been performed with the intent of validating generic HRQoL instruments in patients with neonatal surgical disease. Furthermore, a select number of disease-specific outcome measures have been developed to assess the QoL after treatment of pediatric surgical conditions. For example, in Europe, a proxy version of EuroQOL was found to be feasible and valid in a population of children with imperforate anus.[26] Similar studies have utilized generic quality-of-life measures in children with Hirschsprung's disease,[27,28] anorectal malformations,[29] congenital diaphragmatic hernia (CDH),[30] and neurological impairment requiring gastrostomy or surgical treatment of gastroesophageal reflux,[31] to name a few. Unvalidated questionnaires have also been utilized to assess HRQoL in many conditions treated by pediatric surgeons.[32,33]

Condition-specific HRQoL measures have also been described for children with anorectal malformations and Hirschsprung's disease (HD),[34] as well as for bladder dysfunction, cancer, and inflammatory bowel disease (Table 112.2).[35–37] Very recently, the perspectives of children with EA and their parents of five HRQoL studies have been incorporated into the development of the first condition-specific HRQoL questionnaire for patients with EA.[38] However, this questionnaire needs to be validated in further studies. In summary, very few HRQoL measures, to date, have been specifically validated or developed for use in the neonatal surgical population.

FUNCTIONAL OUTCOMES

Functional outcomes can be measured in a variety of formats. It is a difficult area of health services research to define

Table 112.2 Description of disease-specific HRQoL instruments for use in pediatric age

Instrument	Disease	Applicable age (years)	Dimensions
PinQ	Bladder dysfunction	6–17	Social relation with peers, self-esteem, family and home, body image, independence, mental health, treatment
POQOLS	Cancer	3–18	Physical function and role restriction, emotional distress, reaction to current treatment
IMPACT	Inflammatory bowel disease	9–18	Bowel, body image, functional/social impairment, tests/treatments, systemic impairment
DDL	Obstructive defecation disorder	7–15	Constipation-related, emotional functioning, social functioning, treatments/interventions

Note: DDL: defecation disorder list; PinQ: QoL measure for children with bladder dysfunction; POQOLS: Pediatric Oncology QoL scale.

Table 112.3 Functional outcomes tools

Instrument	Applicable age (years)	Time to complete
FIM℠/WeeFIMII℠	0–18 (proxy)	15–20 minutes (18 items)
FSIIR	0–16 (proxy)	15 minutes (short) 30 minutes (long)
PEDI™	0–7 (proxy)	45–60 minutes (237 items)

Note: FIM℠/WeeFIMII℠: Functional Independence Measure; FSIIR: Functional Status II; PEDI™: Pediatric Evaluation of Disability Inventory.

clearly. In one sense, these outcomes can be measured within the context of a specific disease state and the procedure that is designed to treat that disease. However, for neonatal surgery, the impact of functional outcomes may be inherently distinct from adult conditions. Take, for example, a professional football (soccer in the United States) goalie that can consistently punt the ball to the opposite penalty box. He suffers a knee injury in the prime of his career and must undergo reconstructive knee surgery. A "disease-specific" functional outcome measure following repair could be as simple as assessing his ability to kick the ball that same distance following surgery and physical rehabilitation. From the players' point of view, he is 100% functional if he can kick that same distance without any pain after treatment. However, how do we measure function in this case if he is only able to punt the same distance inconsistently? Also, what if he can punt the same distance, but suffers incredible pain in doing so—is this an issue of QoL, function, or both? Thus, the assessment of "functional outcome" is complex. However, since the sample of premier league goalies who consistently punt a soccer ball nearly the entire length of the football field is relatively small, most generic functional outcome instruments focus on the assessment of individuals with chronic health problems and their ability to "function" in everyday life. These same issues confront the newborn surgeon attempting to study functional outcomes in populations where the congenital malformations are relatively rare. Furthermore, for such measures to have a meaningful individual and societal impact, they must be measured in adult life, where independent functioning is the expectation. The ability to function is distinct from the quality of function, or life. As it relates to health services research, functional outcomes are not necessarily meant to be condition-specific but are related to any of the general domains of functional health in a survey introduced earlier: physical, social, emotional, or cognitive functioning. The following instruments are the three most common tools utilized to measure general functional outcomes in children (Table 112.3).

Functional Status II

The Functional Status II (FSIIR) can distinguish between children with and without chronic health conditions, has acceptable internal consistency and reliability, and correlates with other indicators of illness such as utilization of medical services and illness-related absenteeism.[39] The FSIIR is a 14-item instrument administered to parents to measure their child's capacity to perform age-appropriate roles and tasks in a variety of areas such as communication, mobility, mood, energy, sleeping, and eating. Parents use a three-point categorical scale to indicate the observed frequency of specific behaviors. When impairment in child functioning is described, parents are asked to report whether each specific impairment is due to the child's illness. The total score is the sum of the scores, thus indicating the child's functional status without regard to whether or not the observed impairment is due to the child's illness. The illness score is the sum of the scores indicating the child's functional status with the deduction of points only for impairment related to the child's illness, thus often resulting in a score higher than the total score. The higher the score, the better the functional status.[40]

Pediatric Evaluation of Disability Inventory

The Pediatric Evaluation of Disability Inventory (PEDI) was developed to provide a comprehensive clinical assessment of the essential functional capabilities and performance in children between the ages of 6 months and 7 years. The PEDI was designed primarily for the functional evaluation of young children; however, it can also be used for the evaluation of older children if their functional abilities fall below that expected of a 7-year-old child. The assessment is designed to serve as a descriptive measure of the child's current functional performance, as well as a method for tracking change over time. The PEDI measures both capability and performance of functional activities in three content domains: (1) self-care, (2) mobility, and (3) social function. It has been primarily utilized in the functional evaluation following neurologic insults (i.e., traumatic brain injury or stroke).[41–43]

Functional Independence Measure

The Functional Independence Measure (FIM℠) and its pediatric counterpart (WeeFIMII℠) are standardized instruments initially designed to allow clinicians to document functional performance in children and adolescents with acquired or congenital disabilities.[44] These measures have been approved by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to provide information for the ORYX initiative (a standardized initiative to allow JCAHO to measure performance standards across

accredited organizations) as well as to meet accreditation standards for the Commission on Accreditation of Rehabilitation Facilities.[45]

Other assessments of functional outcome

The aforementioned scoring systems provide generic assessments of child functioning in daily life. However, a pediatric surgeon is often most interested in how a patient compares to his or her age-related peers following a specific intervention performed in the neonatal period. In this regard, disease-specific functional outcome measures have been utilized for a variety of different pediatric surgical conditions. However, "function" can be measured by various instruments and/or objective assessments pertinent to the condition in question. The literature regarding the long-term functional results of CDH illustrates this point.

The collaborative UK Extracorporeal Membrane Oxygenation (ECMO) trial concluded that a policy of ECMO support reduces the risk of death without a concomitant rise in severe disability, defined as an overall developmental quotient of <50 using the Griffiths Mental Development Scales.[46] In another study of infants with severe CDH (those that required ECMO support), survivors displayed mild neuromotor and cognitive delay in development at 24 months of age as measured by impairments in mean Bayley Mental Developmental Index and Psychomotor Developmental Index scores.[46] Both of these studies utilized cognitive functioning scores to report on the functional outcomes of infants with CDH.

Other assessments of functional outcome may be related to objective physiologic measurements. In a study of 23 adult survivors of CDH, pulmonary function tests, diffusion capacity, and a cardiopulmonary exercise test (CPET) were performed. The FEV1 and FEF25%–75% were found to be lower in CDH survivors. Despite these abnormalities, during CPET, percent predicted workload and percent predicted maximal oxygen uptake were normal in most of the patients.[47] In another study of functional respiratory outcomes of CDH patients treated in the perinatal period, 26 adolescent survivors and age- and gender-matched controls were subjected to pulmonary function testing. Significant differences were found in nearly every spirometric measurement.[48] Thus, as function relates to pulmonary mechanics in the CDH population, functional outcomes can be construed as favorable or unfavorable depending on the measure utilized.

In general, functional outcomes refer to things that are meaningful to the patient in the context of everyday living. However, for pediatric surgeons, function may be best related to how well the operation can recapitulate the "normal." In that regard, condition-specific functional outcomes are also worthy to gauge the "success" of a neonatal operation. For example, it would be helpful to the pediatric surgeon to know what percentage of patients with a Type C EA can eat any food without dysphagia in adult life. Similarly, anorectal function (fecal continence) after the period where toilet training is typically achieved is an especially significant outcome measure for patients with anorectal malformations and HD. These types of disease-specific measures are helpful for patients and their families as they consider the long-term functional issues related to the congenital malformations we are charged with treating. In the final analysis, both disease-specific and generic functional outcomes have merit in the long-term assessment of patients with neonatal surgical conditions.

COST-EFFECTIVENESS AND UTILITY MEASURES

A panel convened in 1993 by the U.S. Department of Health and Human Services suggested that standardized outcomes analyses be conducted to evaluate the cost-effectiveness of medical care.[49] One way to directly compare relative treatment effectiveness is to examine the impact of interventions on the utility gained. Cost–utility analysis fulfills this requirement.[50] In this type of analysis, health treatment effects are most commonly measured regarding quality-adjusted-life-years (QALYs) gained. Preference-based instruments allow one to compare interventions and treatment regimens for a given condition in this manner. Such analyses have become popular for examining the economic consequences of disease and the medical and surgical interventions aimed at treating such problems. A QALY takes into account both quantity and QoL generated by healthcare interventions. It is the arithmetic product of life expectancy and a measure of the quality of remaining life years. A QALY places weight on time during different health states such that a year of perfect health is worth a score of 1, whereas death receives a score of 0. Health states considered to be worse than death receive a score below zero. The strength of QALY analysis is the fact that it provides a common currency to assess the extent of benefit gained from interventions to improve the QoL. A cost–utility ratio can be calculated from a QALY assessment combined with the cost of treatment for the condition. For example, a disease that reduces the QoL by one-half will take away 0.5 QALYs over the course of 1 year. If it affects two people, it will take away 1.0 QALY (equal to 2×0.5) over a 1-year period. Medical treatment that improves the QoL by 0.2 for each of five individuals will result in a score of 1 QALY if the benefit is maintained over a 1-year period. Using this system, it is possible to express the benefits of various interventions by showing how many QALYs they produce versus the total economic cost of the intervention.[51]

Utility and cost ultimately are important components of healthcare policy formulation. Using the common metric of QALYs also allows one to introduce QoL into the direct cost comparison of programs. This approach provides a framework within which to make policy decisions that require selection between competing alternatives. Importantly, these types of analyses are potentially influential in determining the extent of funding for particular pediatric interventions.[13] The Health Utility Index (HUI), the Quality of

Table 112.4 Utility instruments

Instrument	Applicable age (years)	Time to complete
QWB	5–18 (self and proxy)	10 minutes
HUI:2	6–18 (self and proxy)	3–10 minutes
EQ-5D	5–18 (self and proxy)	1–2 minutes

Note: EQ-5D: Euro Quality of Life; HUI:2: Health Utilities Inc.; QWB: Quality of Well-Being Scale.

Well-Being Scale (QWB), and the EQ-5D are three examples of utility-based measures developed for and validated in pediatric populations (Table 112.4).

Quality of Well-Being Scale

Developed by researchers at The University of California, San Diego, the QWB assesses a patient's objective level of functioning in three areas: mobility, physical activity, and social activity.[52] An important distinction is made between "functional ability" and "functional performance"—whereby a patient is asked to report activity performed rather than what can be performed. The scoring of the instrument utilizes population-derived preference weights. Current studies are addressing the validity of the QWB-SA translated into Spanish, German, Italian, Swedish, French-Canadian, and Dutch.

Health utilities index

The HUI (HUI2, version 2; and HUI3, version 3) is a family of health status and preference-based HRQoL measures suitable for use in clinical and population studies.[53] Both HUI2 and HUI3 focus on capacity rather than performance. Each includes a health status classification system, a preference-based multiattribute utility function, data collection questionnaires, and algorithms for deriving HUI variables from questionnaire responses. The attributes of health status included in HUI were chosen on the basis of their importance to people. HUI utility scores are based on the preferences of the community. HUI2 consists of seven attributes: sensation (vision, hearing, speech), mobility, emotion, cognition, self-care, pain, and fertility.[54] Similarly, HUI3 consists of eight attributes: vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain.

EQ-5D

Established in 1987, the EuroQOL Group initially comprised a network of international, multilingual, and multidisciplinary researchers from seven centers in Finland, the Netherlands, Norway, Sweden, and the United Kingdom. Currently, the group has expanded to researchers from Canada, Denmark, Germany, Greece, Japan, New Zealand, Slovenia, Spain, the United States, and Zimbabwe. The EQ-5D is a generic measure of health status that provides a simple descriptive profile and a single index value that can be used in the clinical and economic evaluation of healthcare and in population health surveys. The EQ-5D system consists of five dimensions: mobility, self-care, usual activity, pain/discomfort, and anxiety/depression. Each dimension has three levels designated simply as no problem, some problem, or severe problem, and subjects are asked to check the level that is most descriptive of their current level of function or experience in each dimension. These five dimensions yield 243 possible distinct "health states" comprising the classification system. The classification scheme has been assigned standardized scores derived from population-based samples of respondents asked to assign values to subsets of the 243 states. A set of valuation weights has been derived from a U.S. sample.[55]

Although several measurement instruments have been developed to measure utility in children, measurement methods are seemingly fraught with inconsistencies and biases.[56] Indeed, a study of cost–utility analyses in the medical literature between 1976 and 1997 recommended the need for more consistency and clarity in reporting.[57] In response to such criticisms, the Paediatric Economic Database Evaluation Project was conceived to promote research into pediatric health economic methods. In recent years, standard methods for the conduct of economic evaluations have evolved to improve allocation decisions that are unique to the pediatric population. The database contains over 2776 citations from January 1, 1980, to December 31, 2014, and continues to be updated. Consistent with use in allocation decision-making, only full economic evaluations are accepted for inclusion.[58]

Long-term outcomes in specific neonatal surgical disease

Assessment of outcome is an important part of the practice of neonatal surgery. The current tools available to quantify the QoL, function, and cost–utility have changed dramatically over the last decade. However, this area of health research remains in its infancy where patients with neonatal surgical conditions are concerned. Unfortunately, there are a few studies in pediatric surgery that address long-term outcome. This offers an opportunity for further research, yet represents a host of difficulties. Information on long-term outcomes is difficult to obtain as studies require the meticulous collection of data over many years and are hampered by the lack of long-term follow-up (especially for those children who do well!), and attempts to corral a mobile patient population require efforts beyond the willingness or resources of most pediatric surgeons. Furthermore, relatively few

clinical interventions and treatments in pediatric surgery are supported by adequately powered randomized controlled trials—which may undermine the subsequent analysis of long-term outcome. In many cases, the specific short- and long-term morbidities of each congenital malformation and its respective operative treatment have been previously addressed in the specific chapters of this text. However, we will cover some of the salient long-term standard and modern outcome measures of the most common neonatal thoracic and abdominal surgical conditions, and propose future opportunities to further our understanding of the ramifications of these malformations and the operations utilized to treat them.

LONG-TERM OUTCOMES FOR SURGERY IN THE NEWBORN PERIOD

General considerations—prematurity and low birth weight

The neonatal period is defined as the period after birth within the first 28 days of life. Indeed, no other patient demographic in medicine has achieved such a dramatic improvement in survival over the last 30 years as that of the premature neonate. Today, the survival of very low birth weight (VLBW) infants (birth weight less than 1500 gm) has increased to over 80%. Furthermore, patients weighing less than 1 kg (extremely low birth weight) have realized a survival in as many as 70%. These increases have occurred as a result of many substantive improvements in perinatal care and the expertise and methods by which that care is delivered. However, as the number of deaths from sepsis and the sequelae of group B streptococcal infection and chorioamnionitis has declined, the proportion of mortality due to congenital anomalies has increased in both the United States and the United Kingdom. The most recent national vital statistics report released by the United States Centers for Disease Control in 2014 states that the infant mortality rate of 5.96 per 1000 live births—a historical low—was 13% lower than in 2003. During the same period, the neonatal mortality rate (death rate among infants under 28 days, a subset of infant mortality) decreased 13% to 4.04 per 1000 live births, and the postneonatal mortality rate (death rate among infants 28 days through 11 months, a subset of infant mortality) declined 13% to 1.93 per 1000 live births. However, the leading cause of death in the group under 28 days of postnatal life is attributed to congenital malformations. Indeed, the yearly prevalence of congenital malformations increased from 4.0% of infants born in 1998 to 5.6% in 2007, and congenital malformations remain an important cause of neonatal morbidity and mortality among VLBW infants.[59]

In England and Wales, congenital anomalies are the second commonest cause of infant deaths overall with a rate in 2007 of 1.39 per 1000 live births; and they are the leading cause of deaths in the postneonatal (>28 days) period at 0.52 per 1000 live births.[60] For appropriately grown infants (not suffering from intrauterine growth retardation [IUGR]) between a birth weight of 1500 and 2500 g, the mortality rate remains less than 10%. Below this weight, mortality rates incrementally increase, and survival below 500 g is uncommon. Today, the gestational age at which there is a 50% chance of survival has declined to 25 weeks.[61] Perhaps the most salient long-term outcome as it relates to prematurity and low birth weight is the incidence of impairment, disability, and handicap. According to the World Health Organization, "long-term impairment" includes any loss or abnormality of psychological, physiological, and anatomic structure or function. "Disability" is defined as any restriction of ability to perform an activity within the range considered normal for a human being. Disability reflects the consequence of impairment regarding functional performance and activity. Finally, a "handicap" is a disadvantage for a given individual resulting from an impairment or disability that limits fulfillment of the role that is normally based on age, sex, social, and cultural factors.[62] The most significant major disability affecting premature infants is cerebral palsy (CP). CP is defined as a permanent impairment of voluntary movement or posture due to damage to the developing brain. It may involve one limb (monoplegia), both lower limbs (diplegia), or all four (quadriplegia). In patients weighing less than 2 kg at birth, the incidence of CP at the age of 2 years was 8% in a geographical study of 1000 children.[63] Very and extremely low birth weight survivors are also at an increased risk for long-term visual impairment, such that approximately 5% of infants in this category are "blind." Retinopathy of prematurity is the most common cause of poor visual outcome. However, cortical blindness can occur from damage to the occipital cortex due to periventricular leukomalacia or optic atrophy as a result of hydrocephalus. Cryotherapy for retinopathy of prematurity is an effective treatment, reducing the chance of severe visual loss by 50%, and this treatment has led to an improvement in long-term visual handicaps associated with prematurity.[64] Sensorineural hearing loss (SNHL) is also a problem in survivors of premature birth. This is most frequently seen in survivors with persistent pulmonary hypertension, and high incidences are widely reported in survivors of extracorporeal life support (ECLS). In a longitudinal study of 1279 extremely premature children (gestational age ≤28 weeks; birth weight <1250 g), Robertson et al.[65] found permanent hearing loss in 3.1% and severe to profound loss in 1.9%. Among affected children, hearing loss was delayed in onset in 10% of them and was progressive in 28%. Prolonged supplemental oxygen use was the most important marker for predicting hearing loss.[65] In modern intensive care units, all infants are screened for hearing loss. Early diagnosis guides appropriate support and improves language development later in life. Whereas CP is clearly one of the most devastating long-term consequences of prematurity, cognitive impairment is a more common adverse outcome.[66] The intelligence quotient (IQ) in long-term survivors of VLBW gestations is shifted one standard deviation lower when compared to normal birth

weight controls, and a significant number of these children suffer from attention deficit or hyperactivity disorders when compared with controls. However, even with an IQ in a normal range, the VLBW survivor is more likely to require special educational provisions. Also, small for gestational age infants suffer from a negative impact on school performance; 25% of such infants in 1985 were failing at school at age 10 years compared to 14% of children who had been weight appropriate for gestational age.[67] Nevertheless, small for gestational age survivors report "adequate" satisfaction with life despite the fact that these individuals are less likely to secure professional or managerial employment.[68] Finally, poor motor coordination, altered manual dexterity and balance, short attention span, and visual impairment are coexistent and together significantly impair the child's ability to function in school. The highest proportion of these adverse neurodevelopmental outcomes are seen in those treated with the highest acuity of care (i.e., ECLS).[69–71]

General considerations—psychological effects of neonatal surgery

In addition to the consequences of prematurity and low birth weight, the psychological consequences of surgery performed within the first 28 days of life should not be overlooked. Studies on the effects of hospitalization on young children show that between 6 months and 4 years of age, children will most likely demonstrate short-term emotional and behavioral problems during that admission, and later psychological disturbances were associated with repeat hospital admission, as well as those hospitalizations lasting for more than a week. Based on these observations, Dr. Loraine Ludman and colleagues at the Great Ormond Street Hospital for Children began a prospective longitudinal study to examine the psychological effects of major neonatal surgery on infants and their families. The infants studied were born at term and required major surgery within the first 28 days of life. These infants were compared to a carefully matched group of healthy newborns not requiring neonatal surgery. Interestingly, very early hospitalization and periods of separation did not differentiate between the case–control pairs at 12 months of age. However, by 3 years of age, the rate of behavioral disturbance was approximately 2.5 times greater among the patients undergoing surgery in the first 28 days of life compared to the control group (30% versus 11.5%). At that stage, the number of operative procedures that the child underwent was the strongest predictor of outcome on both verbal and nonverbal IQ measures. The two predominant factors associated with difficulty in the mother–child relationship were a lengthy first admission (more than 25 days) and/or repeat hospital admissions. In longer-term follow-up between 11 and 13 years of age, emotional and behavioral problems were more frequent in the surgical group than among the controls based on parent and teacher reports. These data suggest that surgery and repeated admissions in early childhood have long-term effects on emotional behavior adjustment. However, although a third of children were affected by the chronic nature of their condition in their preschool years, at early adolescence, only a small proportion of those included in the dataset were regarded as having a "chronic condition." Also, the youngsters all rated themselves as "well adjusted," and there were no differences between the two groups regarding self-esteem and depression self-report scales. These data raise the need for long-term focused psychological support for children and their families who care for children with major congenital anomalies requiring surgery in the neonatal period.[72–74]

Thoracic surgery—general considerations

Some conditions diagnosed within the first 28 days of life require access to the thoracic cavity by way of thoracotomy or thoracoscopy. Neonatal thoracotomy is typically well tolerated in the short term. The recovery and return to normal physiologic function following neonatal thoracotomy is in contrast with that observed in adults—in which long-term pain and disability are more often realized in older patients. However, rapid neonatal "recovery" must be tempered by the potential for long-term chest wall growth abnormalities resulting from thoracotomy. Several types of orthopedic deformities have been described following neonatal thoracotomy, including scoliosis, rib deformities and synostosis, and shoulder deformities. Jaureguizar et al.[75] reported on 89 patients operated for EA via standard right posterolateral thoracotomy with a follow-up of 3–16 years. Of these, 32% had significant musculoskeletal deformities including "winged scapula," marked asymmetry of the thoracic cage from atrophy of the serratus anterior, rib fusion, and severe thoracic scoliosis.[75] Chetcuti et al.[76] reported on a similar experience in the study of 232 patients with esophageal congenital anomalies without preexistent congenital vertebral anomalies who underwent neonatal thoracotomy. In this series, 33% of patients later developed chest wall deformities, and 8% were reported to have scoliosis.[76] One of the purported benefits of minimally invasive access to the chest (thoracoscopy) for lung resection and repair of EA is the potential benefit of limiting this chest wall morbidity. The long-term outcome of minimally invasive access to the thorax requires assessment of this possible benefit. Because of the above concerns, many pediatric surgeons today utilize a muscle sparing thoracotomy through the auscultatory triangle while preserving the latissimus dorsi and serratus anterior musculature for infants. The long-term benefits of this type of approach also have not been reliably compared to that of a standard muscle splitting thoracotomy. Both of these newer approaches to thoracic access offer opportunities for the pediatric surgeon to assess the potential benefits of modern surgical technique to the long-term outcomes of neonatal thoracic surgery.

MALFORMATIONS OF THE TRACHEOBRONCHIAL TREE

Subglottic stenosis did not become an issue until prolonged endotracheal intubation and ventilation of neonates became commonplace in the mid-1960s. As survival of low birth

weight infants increased, so did the number of patients with acquired laryngotracheal stenosis. Today, advances in the equipment utilized for neonatal endotracheal intubation, tube stabilization, and the recognition of the deleterious effects of prolonged transglottic instrumentation have decreased the incidence of laryngotracheal stenosis to less than 10%. In patients suffering significant laryngotracheal stenosis, the surgical options largely depend on the grade of stenosis realized. The functional outcomes of laryngotracheal reconstructive (LTR) surgery are clearly critical in the determination of long-term success. Studies evaluating exercise tolerance, speech, swallowing, and voice are at this point limited, owing to the relatively recent advances in the surgical correction of these disorders. Early studies of voice function after LTR surgery were entirely subjective assessments; however, recent studies in children have paired subjective observations with objective measurements.[77]

PULMONARY RESECTION

Pulmonary resection in the neonatal period may be undertaken for a congenital pulmonary airway malformation (formerly "CCAM"), pulmonary sequestration, or congenital lobar emphysema. The most significant long-term outcome facing patients undergoing neonatal pulmonary resection is that of respiratory function. Ayed and Owayed[78] reported on the safety of lung resection in the neonatal period for congenital malformations and found that none of the patients had physical limitations at a mean follow-up of 4 years. Also, Caussade et al.[79] reported normal spirometry values for vital capacity in 27 patients who underwent neonatal pulmonary lobectomy. Neonates undergoing lung resection can expect to have normal vital capacity due to the compensatory growth of the remaining lung, and most studies indicate that few children are functionally impaired by lung resection performed in the neonatal period. In addition, in patients who undergo pneumonectomy prior to the age of 5 years, ventilatory capacity is only minimally reduced when compared to that predicted for an individual with a complement of two normal lungs suggesting that "lung growth" occurs well beyond the neonatal period as a result of compensatory pulmonary hyperplasia.[80] Furthermore, no correlation could be found between age at lobectomy and future pulmonary function.[81] It appears that normal postnatal growth of lung parenchyma at the gas exchange (alveolar) level up to about 7–8 years of age contributes most of this additional reserve, as there is not regeneration of conducting airways. Whereas functional outcome studies have been limited in patients undergoing pulmonary resection in the neonatal period, reports of HRQoL are noticeably absent in this patient cohort. To date, there is no literature classifying the HRQoL of infants undergoing neonatal pulmonary resection.

MALFORMATIONS OF THE ESOPHAGUS

One of the most commonly performed operations undertaken by the pediatric surgeon in the neonatal period is the repair of EA and/or tracheoesophageal fistula. Mortality rates in patients with Waterson Risk Groups A and B EA are well below 5% overall. Today, the nature of coexisting anomalies that determine survival is best described by a newer risk stratification taking into account birth weight and the presence of cyanotic congenital heart disease.[82] Early surgical complications such as anastomotic leak, disruption, or stenosis are often associated with a favorable short-term outcome when adequately treated. In the long term, dysphagia and food impaction are the most common foregut issues facing the child with repaired EA. The motility of the esophagus is inherently abnormal to some degree in all patients despite "adequately" repaired EA.[83] Although symptoms of "choking with feeding," odynophagia, and "food impaction" are relatively common during childhood following EA repair, these problems tend to decline with age. Those who have persistent difficulties with swallowing are more likely to have or have had an esophageal stricture or significant gastroesophageal reflux. Today, radial balloon dilation of the esophagus under fluoroscopic control and medical and/or surgical control of reflux disease are useful adjuncts in the prevention of these long-term sequelae. Indeed, most adult survivors with repaired EA have minor persistent gastrointestinal symptoms such that less than 10% report dysphagia that occurs once a day, and the majority report no symptoms of gastroesophageal reflux.[84] While it is believed that persistent gastroesophageal reflux in patients undergoing EA repair contributes to dysphagia, there is little objective evidence of this. The majority of neonatal gastroesophageal reflux disease is a transient problem, can be mostly treated medically, and abates by childhood. However, a few studies report persistent gastroesophageal reflux in postoperative children after esophageal repair,[85–88] which in consequence, if untreated, can lead to esophagitis, metaplastic epithelial changes (gastric metaplasia or intestinal metaplasia), and esophageal adenocarcinoma. The metaplastic columnar mucosa, the so-called Barrett's esophagus, is found according to one study in 42% of EA patients.[87] Barrett's esophagus (BE) becomes an important risk factor for developing esophageal adenocarcinoma, and it is suggested the prevalence of BE in EA patients is higher and that it occurs at a much younger age.

Cancer in the upper gastrointestinal tract in EA patients has been described in 10 cases, of which 8 were esophageal carcinoma and 2 squamous cell carcinoma not related to the native esophagus (related to the lung and to a subcutaneous skin tube reconstruction).[89–95]

Given the high prevalence of BE, the early development of esophageal cancer, and the possible absence of symptoms in EA patients, surveillance programs seem warranted. Prospective long-term follow-up cohort studies, including endoscopic data of adult EA patients, are limited, and guidelines for follow-up are lacking.

Although adults with repaired EA may be at increased risk for developing esophageal malignancy, it is too early to tell whether or not the history of EA affects the incidence of esophageal carcinoma later in life. The concern is that esophageal dysmotility, poor esophageal clearance,

and reduced lower esophageal sphincter pressure, even in the absence of symptoms, may lead to the development of Barrett's esophagus.

Several screening strategies have been suggested as a clinical screening in all patients aged 15–25 years, with endoscopy performed if any gastroesophageal reflex symptoms are present.[96] Another study suggested endoscopic surveillance at the ages of 15, 30, 40, 50, and 60 years, with intensification of this protocol if pathological observations are made: yearly in case of BE and 5-yearly in the presence of esophagitis, gastric metaplasia, severe esophageal strictures, recurrent tracheoesophageal fistula (TEF), severe GER symptoms, or the need for continuous antigastroesophageal reflex disease (GERD) medication.[86] Other endoscopy protocols suggest screening in all adults, from the age of 30 years for patients with significant primary surgery complications; from the age of 20 years, regardless of symptoms (5-yearly until the age of 30 years, 3-yearly until the age of 40 years, 2-yearly after 40 years of age); and screening once before adulthood with surveillance through adulthood with 5- to 10-year intervals (3-yearly in case of BE or twice a year with dysplasia).[87,88,93,97]

However, as more survivors make their way into adult and elderly life, this certainly should be a consideration for pediatric and adult surgeons caring for patients who have undergone EA repair. Follow-up should be vigilant and lifelong until the risk of malignant degeneration in these patients is better delineated.

To date, five studies have examined the HRQoL in children and adolescents after repair of EA.[33,98–101] These studies showed HRQoL experiences among children with EA and revealed that condition-specific HRQoL parameters concerned various aspects ranging from participation in play and sport, nutritional intake, social and emotional concerns, to body image issues. Several HRQoL experiences like those of stigma, isolated emotions, and impact of medical treatment are similar to those of children with other chronic health condition. As previously reported, children with EA suffer from feeding difficulties and growth retardation, particularly at early ages. Additionally, this study provides information that among EA children up to 17 years, feeding challenges and growth retardation can give rise to social and emotional strains such as being different from peers and being teased. Moreover, EA possibly affects the child's relationships and interactions with other people,[98,99] although improvement in the age group 8–13 years has been described.[100] Children with EA independent of surgical scar(s), scoliosis, or a winged scapula experienced concerns that were related to discomfort among others, to the sense of being different, or to dissatisfaction because of their appearance. Half of adults with EA had complaints of surgical scar(s), and 11% were disturbed by a disfigured or winged scapula. After esophageal replacement (mean age of patients was 34.5 years), esthetic results were the main problem, especially during adolescence. From the perspective of the pediatric surgeon, knowledge of HRQoL issues of significance to the EA children may improve the decision-making process of surgical technique and the patient–surgeon communication during the postoperative follow-up. It may permit identification of reduced HRQoL, presentation of well-directed patient and parent information, provision of relevant family support services, and, importantly, optimization of the postoperative medical management. A follow-up plan directed by the patient's needs and concerns might improve long-term health and HRQoL outcomes.

The perspectives of children with EA and their parents have been incorporated into the development of the first condition-specific HRQoL questionnaire for patients with EA.[38] According to the reported HRQoL experiences, EA interacts with various aspects of the child's life, especially among children with complex forms of EA. In addition to HRQoL issues of eating and drinking, social dimensions of relationships and interactions with other people appear to be prominent condition-specific parameters.

There are fewer problems more technically challenging for the pediatric surgeon than the patient with long-gap EA (LGEA). In the short term, the surgeon must decide on the appropriate management strategy for reconstruction of the esophageal conduit. There is a consensus among most pediatric surgeons that the conservation of the native esophagus is associated with the best postoperative results, and every effort should be made to conserve the native esophagus, as no other conduit can fully replace its function in transporting food from the oral cavity to the stomach satisfactorily. In the last 70 years, a number of innovative and sometimes controversial techniques have been introduced to reduce the distance between upper and lower esophageal segment to allow an anastomosis.[102] In 1981, Puri et al.[103] reported the observation that the spontaneous growth and hypertrophy of the esophageal segments in LGEA occur at a rate faster than overall somatic growth, in the absence of any form of mechanical stretching. The stimuli for such natural growth are the swallowing reflex and the reflux of gastric contents into the lower esophageal pouch.[104] Puri et al.[105] further noted that the maximal natural growth of the esophageal segments occurred during the first 8–12 weeks, and therefore, they suggested that the ideal time for delayed primary anastomosis (DPA) is when the infant is about 16 weeks old. A recent meta-analysis investigating long-term outcome of DPA showed that the majority of patients were able to feed normally and have normal growth and development curves after DPA.[102] However, the potential risk of Barrett's metaplasia highlights the need for continued long-term follow-up with regular endoscopic surveillance protocols as outlined above.

Although it is widely accepted that the optimal esophageal conduit is the native esophagus, some circumstances are prohibitive and surgeons use either colon, native stomach, or jejunal grafts to bridge abbreviated esophageal segments. Techniques for sequential and gradual elongation of the native esophagus such as those popularized by Foker et al.[106] and Kimura et al.[107] appear to offer favorable short-term surgical outcomes in the institutions where they are employed. These results have proven difficult to replicate,

and the long-term adverse sequelae of either esophageal replacement or native esophageal lengthening remain significant. In a recent study from the Great Ormond Street Hospital, the vast majority of patients undergoing LGEA repair had long-term issues with gastroesophageal reflux.[108] A report from The Children's Hospital of Los Angeles concluded that patients with a gastric conduit had a lower overall complication rate without evidence of conduit ischemia when compared to those with a colonic interposition; however, the incidence of long-term adverse physiologic sequelae was significant. In a review of published studies for esophageal replacement in children by Arul and Parikh,[109] there was no significant difference in either early or late complications associated with the different type of conduits utilized for interposition. However, the authors did note that larger series tended to have lower complication rates than those of small series, likely reflecting the association between clinical expertise and experience and outcomes in larger surgical centers.

The short- and long-term physiologic outcome of EA and tracheoesophageal fistula could be considered favorable. However, little data exist about HRQoL in this cohort of patients. Furthermore, the long-term follow-up of patients with EA and the impact of Barrett's esophagitis and later development of adenocarcinoma is yet to be fully realized and mandates vigilant postoperative follow-up and a surveillance program that should be overseen by a practicing pediatric surgeon.

CONGENITAL DIAPHRAGMATIC HERNIA

CDH has been widely studied. The mortality rate and adverse sequelae in survivors of CDH remain significant compared to the other commonly treated newborn surgical conditions addressed by the pediatric surgeon. Historically, the long-term follow-up of patients with CDH was sporadic and uncoordinated. This likely led to an underestimation of the number and severity of problems affecting survivors of CDH repair. Data from long-term follow-up studies identify several potential morbidities involving a number of different organ systems including pulmonary, cardiac, neurologic, gastrointestinal, urogenital, and musculoskeletal systems. Today, it is recognized that these patients are best cared for in a multidisciplinary setting where coordinated follow-up care involving multiple specialties is possible.[110,111] Although this is not a widespread practice among pediatric surgeons, large pediatric centers are encouraged to develop these types of outcome clinics to coordinate follow-up and address ongoing physiologic concerns among survivors of CDH.[112] Indeed, the most remarkable accomplishment in dealing and caring for a patient with CDH is the improved survival to hospital discharge during the past decade.[113,114] However, while some authors have reported survival figures approaching 90%,[115] the current overall survival in the Unites States is 70% among 2676 live-born infants from 50 tertiary centers.[116]

The Congenital Diaphragmatic Hernia Study Group (CDHSG) is an international consortium of centers that prospectively collect and voluntarily contribute data about live-born CDH patients they manage. In total, 8279 patients were in the database as of June 2014. The vast majority are neonates (7998; 96.6%), although 281 patients were late presenters. Overall mortality decreased from >35% in 1995 to under <30% in 2013.

They reported 2014 data of more than 5000 infants (including 1127 preterm infants), compiled for over 15 years. The overall survival rate of infants in the cohort was 68.7%; term infants had a significantly higher survival rate than preterm infants: 73.1% versus 53.5%, respectively. Mortality was inversely proportional to estimated gestational age (EGA) at birth. The overall survival rate for the most premature infants, ≤28 weeks EGA, was 31.6%. Preterm infants were twice as likely as term infants to have chromosomal anomalies or cardiac defects. Whereas 86% of term infants underwent operative repair, 69% of preterm infants underwent repair. The percentage of infants who underwent operative repair decreased with decreasing gestational age.[117]

For those CDH patients who do survive to hospital discharge, long-term morbidity is a function of the severity and laterality of the defect as well as the need for extracorporeal membrane oxygenation (ECLS).[71,118,119]

Pulmonary morbidity is perhaps the most significant problem during early childhood in survivors of CDH.[120–124] Ventilatory barotrauma, bronchopulmonary dysplasia (BPD), and chronic lung disease play a larger role than previously suspected in both mortality and morbidity of those patients with CDH.[113,125] The prevalence of BPD was reported to be 41% in CDH neonates who survived until day 30. Furthermore, the severity of chronic lung disease in CDH survivors may require prolonged ventilator support and tracheostomy. CDH survivors may also suffer from recurrent respiratory tract infections in infancy and early childhood.[111,120,126] Nearly 60% of survivors require some form of medical therapy for reactive airway disease, and long-term obstructive airway disease is demonstrable in approximately 25% of patients at 5 years of follow-up.[127,128] The long-term sequelae of ventilation–perfusion mismatch may also result in significant limitations in exercise tolerance in the adolescent years.[47] Mild airway obstruction and a slightly reduced diffusion capacity for carbon monoxide are observed in most survivors of CDH.

Furthermore, pulmonary hypertension and subsequent right ventricular hypertrophy have been reported in as many as 50% of survivors of CDH treated with ECLS.[129] Nutritional morbidity and growth failure are also, unfortunately, common in patients surviving CDH. In a retrospective analysis of 121 survivors of CDH, over half of the patients were below the 25% for height and weight during the first year of life.[130] Approximately one-third of this population had issues severe enough to require a gastrostomy to provide adequate caloric intake. In two similar studies, gastrostomy tubes needed to be placed in one-third of patients in two survival cohorts due to nutritional morbidity.[70,111]

The need for ECLS and an oxygen requirement at discharge are predictive of growth failure within the first

year of life. Others have reported similar trends in growth failure and nutritional morbidity.[131,132] Oral aversion, foregut dysmotility, and persistent GERD all contribute to the nutritional morbidity of CDH survivors.[123,133] Nearly 40% of babies operated on for CDH will have symptomatic GER, half of whom require antireflux surgery. The most frequently reported predictor of antireflux surgery is the need of diaphragmatic patch repair. Recurrence is more common in patients repaired with a prosthetic patch.[71,120]

Neurocognitive deficits play a significant role in the long-term functional outcome of CDH patients surviving to discharge. Bouman and colleagues reported mild to moderate development delay in more than one-third of CDH survivors followed in a multidisciplinary clinic.[134] Although the neurologic deficits in CDH survivors are the result of the critical nature of the postnatal disease process and its treatment, the contribution of ECLS on neurologic morbidity is of significant concern. The incidence of neurologic abnormalities among all neonatal survivors of ECLS ranges from 10% to 15% and includes CP, hearing loss, seizure disorder, cognitive delay, and vision impairment. However, the use of ECLS in CDH patients confers an increased risk for long-term neurocognitive impairment such that up to 70% of survivors demonstrate some type of neurocognitive deficit.[123,135–137] SNHL has also been frequently reported in CDH survivors.[111] Potential predisposing factors, including the use of ototoxic medications and prolonged mechanical ventilations with high oxygen tensions, lead to SNHL, which is found in CDH survivors treated with and without ECMO, suggesting that the use of ECMO is not the only predisposing factor for SNHL.[65,138] However, several retrospective studies found that the SNHL rate in both ECMO and non-ECMO CDH survivors is between 2.3% and 7.5%,[139–141] which approximates the SNHL rate for all neonatal intensive care unit patients.[111,142]

The orthopedic deformities associated with CDH are also of significance in that CDH survivors are prone to scoliosis and chest wall deformities. Nobuhra reported a 21% incidence of pectus deformities and a 10% incidence of mild to moderate scoliosis in long-term follow-up. These are more common among patients with an initial severe ventilatory impairment and a diaphragmatic defect requiring the need for a prosthetic patch placement.[110,112] It has been observed that these complex long-term issues appear more prevalent as newer support strategies have allowed infants with severe disease to survive.

Regarding HRQoL of CDH survivors, Peetsold et al.[101] have described a significant reduction and perception of general health in survivors of CDH compared to a reference population. Poorer functional status has also been described in CDH survivors in a recent study using the FSIIR tool.[143] These findings have been confirmed by Michel et al.,[144] who also reported a reduced QoL in children after CDH repair. They also report GER as a major marker on impact of QoL in these patients.

Furthermore, in a study from the Children's Hospital of Boston, the impact upon family was found to be profound and longstanding at a median of 8 years after surgery for a subset of CDH survivors with comorbidities and current clinical problems.[145]

ABDOMINAL CONDITIONS

General considerations

Apart from the repair of an inguinal hernia, abdominal conditions in the neonate comprise the majority of work performed by the practicing pediatric surgeon. The long-term outcome of a variety of these conditions is dependent on the method of peritoneal access. The two most significant potential adverse outcomes of laparotomy include adhesive bowel obstruction and incisional hernia. In a study from the Great Ormond Street Hospital, the authors described only four documented cases of incisional hernia in 507 pediatric laparotomies.[146] More salient to the intra-abdominal conditions of the neonate is the potential for adhesive bowel obstruction following laparotomy or laparoscopy. In a study of 649 neonates undergoing laparotomy over 10 years, 8.3% developed adhesive intestinal obstruction requiring surgical intervention.[147] In a similar study from the Netherlands of 304 neonates undergoing laparotomy, adhesive intestinal obstruction occurred in 3.3% of the cases.[148] The indication for laparotomy clearly plays a role in the incidence of postoperative adhesive bowel obstruction. In patients undergoing a Ladd's procedure, 8%–15% of patients experience one episode of postoperative adhesive bowel obstruction.[147] Techniques to prevent intestinal adhesions emphasize minimizing peritoneal trauma and separating potentially involved surfaces. Clearly one of the benefits of minimal access surgery or laparoscopic surgery is in the potential decrease in the incidence of adhesive bowel obstruction, although persuasive long-term data are yet to be realized in supporting this contention. Also, minimally invasive access to the abdominal cavity does result in a postoperative cosmetic result that is preferred by many patients, after they grow into adulthood.[149] Indeed, a noticeable scar can have physical, esthetic, and psychological consequences in children.[150] Cosmetic concerns with regard to abdominal wall scarring are likely to be more important for neonates as they grow into the teenage years. Minimizing these concerns is probably a unique benefit of minimal access neonatal surgery. Other purported benefits of minimal access laparoscopic surgery are that of a decreased inflammatory response, less postoperative pain with a subsequent reduction in the need for postoperative analgesia, and a shorter time to hospital discharge.[151–153]

Gastroschisis

The outcome of the majority of patients affected by gastroschisis is considered good in terms of growth in 75% of the cases[154,155]; the neurodevelopmental outcome seems comparable to gestational age-matched control,[155–157] and there

is the possibility of reproduction and improvement in the overall QoL.[155,158] Although a minority of these infants are affected, the major impact on QoL is the occurrence of short bowel syndrome. Infants affected by short bowel syndrome can be entirely or partially dependent on total parenteral nutrition (TPN). Two-thirds can be weaned off TPN eventually, but the risk of malabsorption and nutritional deficiencies has to be considered and potentially corrected throughout their life. Some of them will remain dependent on TPN, and this anomaly still represents the largest cohort of candidates for intestinal transplantation.

On the other hand, the incidence and morbidity of intestinal adhesions leading to small bowel obstruction are estimated as 15%–27% in gastroschisis, with a mortality rate for bowel obstruction of 15%, and chronic abdominal pain is more common in these patients than in healthy peers.[155,158,159]

There is concern about the impact of adhesions among fertile women. Over 30% of women who undergo reproductive tract summary required readmission for adhesions,[160] but pregnancy is described in patients previously affected by gastroschisis, meaning that for these women, both the reproductive system and abdominal capacity can be adequate. Testicles herniated at birth in gastroschisis patients and relocated into the abdomen at first operation may descend into the scrotum spontaneously in 50% of the cases.[155,161,162] Also, the ability to participate in sports is reported as comparable to healthy peers.[155,163] The last concern is cosmesis. Indeed, 60% of patients without an umbilicus experience some psychological stress.[155,158,164] For this reason, different techniques of umbilical reconstruction are available, mainly performed by plastic surgeons at a later age or pediatric surgeons at initial repair.[155,165,166]

Omphalocele

Some long-term medical problems occur in patients with large omphaloceles. These include gastroesophageal reflux, pulmonary insufficiency, recurrent lung infections or asthma, and feeding difficulty with failure to thrive, reported in up to 60% of infants with giant omphalocele. A third of patients with omphalocele report intermittent abdominal pain persisting into young adulthood. The respiratory insufficiency associated with giant omphaloceles may be secondary to abnormal thoracic development with a narrow thorax and small lung area leading to pulmonary hypoplasia. However, a study looking at the long-term cardiopulmonary consequences of large abdominal wall defects reported normal lung volumes and oxygen consumption on long-term follow-up, although exercise tolerance was slightly reduced.[155,163] In the long-term follow-up, the most widespread concern for patients with omphalocele is cosmesis, with nearly one-half of patients expressing dissatisfaction with the lack of an umbilicus and for the large abdominal wall scar. Recent studies showed how this aspect did not affect the overall QoL, and different techniques of umbilical reconstruction have been proposed mainly by plastic surgeons that are, usually, performed at the request of the patient.[155,163,165,166] However, this issue did not influence the QoL, which is comparable to that of healthy young adults. Parents with fetal diagnosis of omphalocele and parents of newborns with omphalocele should be informed that the high burden of surgical interventions their child will need is likely to result in good health condition in the long term, especially if there are no associated anomalies.[155,167] Patients are at risk for adhesive bowel obstruction, and a small number not treated for malrotation could develop devastating midgut volvulus with subsequent short bowel syndrome. A recent study from the Netherlands indicates that after a high level of medical intervention in early life, minor and giant omphalocele patients report similar long-term results, and the QoL in both groups is comparable to that of healthy young adults.[155,159] For the surviving patients affected by Beckwith–Wiedemann syndrome (EMG syndrome: exomphalos, macroglossia, and gigantism), a regular follow-up must be organized to make an early diagnosis of Wilms or hepatoblastoma tumor, frequently associated with this syndrome.[155,168]

Malformations of the midgut

The most profound sequelae of neonatal surgical conditions involving the midgut involve massive small bowel resection or malabsorption and altered motility. Thankfully, the outcomes of intestinal failure due to short bowel syndrome have changed dramatically over the last 30 years. The development of TPN introduced a new era in the management of children with short bowel syndrome.[169] Although the functional impairment in short bowel patients typically results from an anatomic loss or deficiency of intestinal surface area, it may also occur in the setting of a normal intestinal mucosal surface with perturbations in intestinal absorption, motility, or both. The length of the small bowel is clearly an important predictor of the development of short bowel syndrome; however, the absolute length of "viable" small intestine in the neonatal population may not be an adequate predictor of short bowel syndrome and intestinal failure. Today the consensus for the definition for short bowel syndrome is "intestinal failure as a result of surgical resection or congenital defect or disease which is associated and characterized by the inability to maintain protein-energy fluid and electrolyte or micronutrient balances on an accepted normal diet."[170] Although the amount of bowel that must be lost to produce malabsorption in short bowel syndrome is variable and depends on segments lost and whether the ileocecal valve is preserved, loss of greater than 80% of the small bowel is associated with an increased requirement for enteral nutritional support, decreased overall survival, and the need for further surgical intervention or small bowel transplantation. The neonatal surgical population at risk for developing short bowel syndrome include patients with necrotizing enterocolitis, small intestinal atresia, malrotation and midgut volvulus, and gastroschisis. The complications encountered in short bowel syndrome

are varied in complexity and dependent on a variety of factors. Survival rates reported for short bowel syndrome are influenced by the variable severity of the condition, underlying disorders, and comorbidities. Potential complications are myriad and can include diarrhea and electrolyte disturbances, osteopenia, urinary oxalate stone formation, and TPN-associated liver disease. Also, the achievement of normal somatic growth is a challenge for the patient with short bowel syndrome. The most common causes of mortality following massive small intestinal resection in the neonate include liver failure and sepsis in patients requiring TPN for the majority of their nutritional support. Also, the care of the patient with short bowel syndrome entails substantial economic expense. In 1992, the annual direct cost per home for patients requiring TPN averaged approximately US$100,000.[171] A current cohort study of home parenteral nutrition patients enrolled 1251 patients between August 2011 and February 2014; of the 1251 patients, 15% (n = 188) were infants and children, with a mean age of 4.9 ± 4.9 years and with short bowel syndrome the most frequently reported TPN indication.[172] Also, the complex medical needs and potential complications of the short bowel syndrome have a clear and obvious impact on HRQoL. Although the development of home parenteral nutrition programs has provided greater independence from the hospital for these patients, the responsibility has been shifted to caretakers, which has a profound impact on the family.[173] Unfortunately, there are a few rigorous assessments of the obvious psychosocial impact of this chronic illness on both patients and their families. In adults requiring home TPN, and assessed using the SF-36, social and emotional function, as well as the QoL, were lower in patients requiring home parenteral nutrition associated with a poor QoL compared to those with short bowel syndrome, not on TPN.[174] Although it is intuitive that the QoL for both patients and their parents suffering from short bowel syndrome resulting from neonatal surgical conditions is likely to be low, about normal, the real question is whether or not subsequent surgical interventions may improve the QoL for these patients. Surgical treatment beyond the neonatal period (i.e., Bianchi procedure, longitudinal intestinal lengthening and tailoring, and the STEP procedure) may offer hope for improving the QoL for these patients.[175] Also, developing nonsurgical enteral support strategies beyond the scope of this review offers some promise.

In those patients surviving to small intestinal transplantation, relevant outcome measures include graft and patient survival. In a study from the University of Pittsburgh, the overall patient survival at 5 years following small bowel and intestinal transplantation was 56%.[176,177] At the University of Miami, the 2-year survival rate following small intestinal transplantation between 1997 and 2000 was 46%, although the current 1-year survival is approximately 85% due to improvements in surgical technique and immunosuppressive care.[178] Furthermore, combined transplantation of the intestine and the liver is associated with a 40% graft survival at 5 years,[179] although patient survival is best with isolated intestinal grafts. Both graft and patient survival will likely continue to improve with time. Also encouraging is that HRQoL is improved with intestinal transplantation in patients with short bowel syndrome. Sudan et al.[180] obtained the QoL data from 29 successful pediatric transplant patients and found that patients had comparable CHQ assessments to norms in physical function role, social limitation, general health, bodily pain, role limitations, self-esteem, health, and behavior. O'Keefe et al.[176] reported a significant improvement in overall assessment of QoL in 13 of 26 of the specific domains examined in a cohort of 46 patients after small bowel transplantation. All patients were weaned from TPN by a median of 18 days (range 1–117 days) and from tube feeding by day 69 (range 22–272 days. Their results are promising such that, with continued progress, it can potentially become an alternative to HPN for the management of permanent intestinal failure.[176]

However, the parental assessment was lower than the children in general health perception and role imitation. From a public health standpoint, the financial and emotional costs for caregivers must impact decisions regarding the allocation of medical resources. Long-term outcomes of the surgical treatment of intestinal failure including intestinal transplantation must include assessments of HRQoL, functional outcome, and utility such that families can make appropriate decisions in the neonatal period when faced with the potential for short bowel syndrome.

Malformations of the hind gut

ANORECTAL MALFORMATIONS

The QoL and functional outcomes related to anorectal malformations and their attendant surgeries must be examined with care. Perhaps one of the most notable contributions to the technical practice of pediatric surgery over the last several decades is that of the posterior sagittal approach to the repair of anorectal malformations popularized by Dr. Alberto Pena.[181] However, as advances in surgical technique have allowed us to recreate the anatomic relationships in the perineum with greater short-term "success," the functional outcomes are less clear and appear more dependent on the type of malformation encountered rather than the surgical approach.[182,183] The common relevant "functional" outcome measure is that of bowel control. We are most interested in the ability for a child to defecate normally commensurate with his or her peers. However, the implications of constipation and incontinence also have a significant impact on HRQoL.

In patients with anorectal malformations, associated anatomic malformations of the genitourinary tract, a deficient sacrum (sacral ratio <0.4), or tethered cord not only affect the surgical complexity but also impact the functional outcome and QoL. Continued evaluation after the neonatal period must address the functional sequelae of anorectal malformations. Simply put, two parameters of bowel control are particularly salient to the child with an anorectal malformation. The first is the capacity for voluntary bowel

movements (VBMs). The second is the incidence of soiling or defecation between bowel movements that is uncontrolled and unwanted. The patient who can verbalize a desire to pass stool and uses the commode to pass VBMs has a significant advantage over the individual who has never had VBMs following the repair of an anorectal malformation. The latter patients are physiologically incontinent, that is, with either sensory or muscular failure (or both), and represent a specific category. In terms of soiling, Levitt and Peña[184] have categorized patients with soiling into two "grades." Grade 1 patients soil once or twice a week, where there is a spot or smear of stool in the underwear. The patient who soils every day is considered to have grade 2 soiling. Clinically, this is a straightforward and practical way to categorize patients in long-term follow-up. However, for long-term functional outcome studies, disease-specific scores to assess and quantify bowel control in these patients may be useful for academic purposes. Brandt et al.[185] have developed and validated a continence scale in children with anorectal malformations termed the Baylor Continence Scale. This disease-specific functional outcome measure is administered by recording the responses to 23 questions using a psychometric response analog scale, and the higher the score, the more significant the impact on continence. Higher scores were noted in their population of patients with anorectal malformation (ARM) compared with both enuresis and normal control groups. This type of scoring system may allow pediatric surgeons and physicians to be able to quantitate qualitative data as it relates to the postoperative function following the repair of anorectal malformations. Overall, the most salient predictor of bowel control is related to the type of anorectal malformation, bladder neck fistula, prostatic fistula, and bulbar fistula, since each one of these has a different prognosis.[183,186] Indeed, children with a perineal fistula are likely to be continent but have a higher likelihood of constipation. After anterior sagittal anorectoplasty for perineal or vestibular fistula in females, two of three patients are likely to achieve bowel control comparable to normal in the long term, and the vast majority will be socially continent.[187] Also, the majority of patients with rectal–urethral fistula achieve social continence, although for some this will require intervention with antegrade continence enema (ACE) bowel management. Approximately one-third may report VBMs and complete continence.[188] On the other hand, male patients with a rectobladder neck fistula are more likely to be incontinent of stool compared to their anatomically normal peers.[182,183]

About 50% of female patients with cloacal malformation attain fecal and urinary continence. The remaining half stay clean or dry by adjunctive measures such as bowel management by enemas or ACE channel, and continent urinary diversion or intermittent catheterization. Problems related to genital organs such as obstructed menstruations, amenorrhea, and introitus stenosis are common and often require secondary surgery. Encouragingly, most adolescent and adult patients are capable of sexual life despite often complex vaginal primary and secondary reconstructions. Also, cloacal malformation does not preclude pregnancies, although they still are relatively rare. Pregnant patients with cloaca require special care and follow-up to guarantee uncomplicated delivery and preservation of anorectal and urinary functions. Cesarean section is recommended for cloaca patients. The self-reported QoL of cloaca patients appears to be comparable to that of female patients with less complex anorectal malformations.[189,190]

Assessment of comprehensive HRQoL in patients with ARM has been undertaken in a number of studies. The Euro QoL score has been validated in children with a history of anorectal malformation and repair.[26] In addition, disease-specific QoL questionnaires have been developed.[34,191,192] In the Brandt study from 2007, patients with anorectal malformations, in general, had a lower HRQoL score (CHQ) compared to both enuresis patients and a normal control group. Utilizing a disease-specific QoL questionnaire, Grano et al.[193] found that adults with previously repaired ARMs reported significantly lower emotional functioning and problems in the area of body image and physical symptoms when compared to those patients in the control group. In Hartman et al.'s[192] study, HRQoL is directly related to the nature and severity of the anorectal malformation. Children and adolescents with anorectal malformations reported better QoL over time. This could be attributed to coping mechanisms, utilization of a bowel management program, or more specific attention by the medical community to addressing the psychological and physiological needs of these patients in their societal context. However, approximately 13% of male ARM reported erectile dysfunction, while 50% female ARM reported sexual dysfunction not related to the QoL or type of malformation. Both ARM patients felt a need for better addressing of their sexual concerns during medical care.[194] Although psychological functioning is typically an attribute of HRQoL, specific psychological effects of anorectal malformations and their repair are also clinically relevant. A high proportion of children with previously repaired ARMs have clinically significant emotional problems based on psychiatric diagnostic interviews. Despite normal intelligence, more than half of these patients received special education or remedial teaching. In addition, problems with sustained attention were found. These findings are important for long-term care.[195] Approximately 29% of children were found to have a psychiatric disorder, with 19% having disorders severe enough to influence their daily lives.[196,197] This was significantly higher than the general child population in the United Kingdom, where the rate of a significant psychiatric disorder is 10%. Other studies have delineated similar findings.[198,199]

HIRSCHSPRUNG'S DISEASE

During the past decades, one-stage transanal endorectal pull-through (TEPT) has become one of the most commonly performed procedures for infants with Hirschsprung's disease (HD). This can be performed totally transanally or in combination with transabdominal colonic mobilization using laparotomy or laparoscopy.[200–203] The recognition of

enterocolitis and its prompt treatment have decreased the short-term morbidity and mortality associated with this disorder. Early diagnosis of the disease, improvements in neonatal and anesthetic care, and surgical technical advancement have allowed for successful and prompt surgical treatment in the neonatal period. However, it has been suggested that bowel mobilization and dissection through the anus has the potential to interfere with anal sphincter integrity and rectal sensation.[200–210] For long-term outcomes, bowel function and continence again become the most salient issues. All of the operations utilized in the treatment of HD carry some risk of constipation. In most series, the severity of constipation following repair decreases with time or resolves. However, it is important to recognize and treat constipation in the postoperative period so as to prevent the long-term functional impairment of the pull-through segment. The occurrence of fecal soiling in patients who have undergone repair of HD can also affect the QoL. Indeed, the complete or partial loss of the rectal reservoir is an inevitable result of pull-through operations for HD owing to the loss or diminution of the high amplitude peristaltic contractions. The incidence of true fecal incontinence is low regardless of the operative technique utilized to address HD. However, when postoperative fecal soiling is critically assessed in childhood, the proportion of patients with some degree of fecal incontinence or soiling is approximately 50%.[27,211–214] In a cohort of 194 patients reported by Menezes and Puri, 68% (n = 132) of the patients had normal bowel function. Also, there was no demonstrable difference in bowel function related to the type of pull-through operation performed. They concluded that the majority of patients with HD continue to have disturbances of bowel function for many years, but most of them will attain normal continence.[215] Another study by Mills et al.[211] assessed functional outcome and HRQoL in 51 patients who had undergone surgical treatment for HD. The mean continence score as assessed by this instrument was 3.34 and categorized as "fair"; however, there was statistically significant improvement in fecal continence scores with age, confirming the previous speculation of improvement for this particular entity with time. Only 7% reported poor fecal continence in the teenage years. Good fecal continence was reported in 80% of teenagers. Utilizing the PedsQL score for HRQoL assessment, these authors found that there was no statistically significant difference between patients with HD and healthy children, either overall or by age group. Interestingly, females had noticeably higher QoL compared to their male cohorts, which also corroborates the long-held view that females with HD may fare better than their male counterparts. They state that fecal continence is a significant predictor of overall QoL in children surgically treated for HD. Although continence tends to improve with age, a number of older children still have ongoing continence problems, and they seem to be a group at risk for impaired QoL.[211] Neuvonen et al.[202] report in a cohort of 79 patients that compared with matched peers, significant impairment of fecal control prevails after TEPT in HD patients during childhood, but symptoms diminish with age. Although overall QoL appeared comparable to controls, impairment of emotional and sexual domains may be present in adulthood.[202] Another cohort of 47 patients demonstrated similar results for QoL in adults when compared to controls. However, some of them have impaired bowel function and QoL.[216]

The long-term outcomes for total colonic aganglionosis (TCA) are clearly inferior to those after surgery for classic HD.[217–220] A specific complication associated with TCA is recurrent enterocolitis, which is a long-term problem among these patients. Reports of enterocolitis post pull-through range from 2% to 55%.[217,220–222] Soiling and fecal incontinence during childhood and beyond are common in TCA patients. At least one-tird of the patients with TCA still suffer from frank fecal incontinence later in childhood or at adolescence.[217–220,223–225] Although the stooling frequency decreases over time, persistent incontinence during day- and nighttime in many of these patients has significant psychosocial implications.[217,220,225] Because of intractable incontinence or recurrent enterocolitis, some patients have opted for permanent or long-term bowel diversion. The percentage of TCA patients ending up to permanent ileostomy ranges between 5% and 18%.[217,220,224]

A significant incidence of day- or nighttime enuresis has been reported in addition to urodynamic abnormalities in children with operated HD. Urinary dysfunction was more common in patients with Swenson or Duhamel operation than in those with endorectal pull-through.[220,226]

Metabolic complications are common after repair of TCA. Growth retardation in childhood is common; it extends to adolescence and affects mainly body weight. In recent reports, severe long-term failure to thrive is, however, uncommon. Body weights and heights below the third percentile have been reported in 5%–15% of patients.[218,220,223,224]

In patients with HD, 11% of males and 53% of females report problems in the psychosexual well-being after pull-through procedures, indicating, as in patients with ARM, a need for better addressing sexual concerns during medical care.[194]

Overall, the long-term functional outcome expectancy of operated HD in terms of fecal and urinary continence is, today, relatively optimistic. Although some degree of bowel dysfunction and defect in fecal continence remain permanent in many patients, a majority of patients reaching adolescence and adulthood can maintain themselves socially continent. In some patients, however, this may require specific bowel management programs.

CONCLUSION

Today, the pediatric surgeon interested in the study of long-term outcomes must be cognizant of the tools available for outcome assessment and choose the instrument most appropriate for the patient population in question. Selection of the appropriate tool to measure an outcome is as important as the act of measuring it. Furthermore, although it is

important to give emphasis to development and appropriate use of outcome instruments, it is imperative that we think of ways in which to improve the QoL or physical, cognitive, or social functioning of our patients. Interventions aimed at improving QoL may play an important adjunct in positively affecting the health of infants and children as they make the transition into adult life (i.e., counseling to teach children better coping skills, support groups, or psychological therapy). Excellent instruments already exist in the realm of generic HRQoL and functional outcomes. Choosing the appropriate instrument is dependent on knowing what the instrument is capable of measuring. National and international organizations dedicated to the surgical care of infants and children would do well to recommend specific generic or disease-specific instruments such that clinicians can utilize equalities of scale when comparing HRQoL or functional outcomes following the surgical correction of congenital or acquired disease. We owe it to our pediatric surgical patients to utilize these instruments, validate them in pediatric surgical populations, and employ strategies to ultimately improve outcomes.

Macroglossia, 349–351
diagnosis, 349
etiology, 349

lymphangioma/lymphatic malformations, 856, 857, 890
management, 349–350
overview, 349
pathology, 349
presentation, 349
surgery, 350–351
Macrolide, 544
Macrophages, 201
biliary atresia and, 750
Macrotrabecular hepatoblastoma, 944t
Magnesium sulfate, in SIP, 660
Magnetic resonance angiography (MRA)
hepatoblastoma, 944
Magnetic resonance cholangiography/pancreatography (MRCP)
bile ascites, 651
CBD, 763, 764f
pyloric duplications, 635
Magnetic resonance imaging (MRI), 1015–1016, 1017f
AVM, 859
CBD, 763
CBE, pelvic floor musculature, 796–797
cervical teratomas, 894, 895
chylous ascites, 649
cloacal exstrophy, 805, 806
congenital mesoblastic nephroma, 960
conjoined twins, 822, 823
FNH, 941
hepatic adenoma, 942
hepatic IHs, 937
hepatoblastoma, 944
hydrocephalus, 991
IH, 849
intraspinal component, 515
KHE, 855, 941
lymphatic malformation, 856
lymphatic malformations and, 887
mediastinal masses, 393
mesenteric and omental cysts, 644
MMIHS, 738
MP, 627
nasal teratoma, 916f
nasal tumors, 912, 913, 914
NCM, 868–869
neuroblastoma, 920
omphalocele and gastroschisis, 783
ovarian cysts, 964
posterior urethral valves, 1105
prenatal diagnosis, 47–48
of neural tube defects and, 978
presacral mass by, 687
pyloric obstruction diagnosis, 537
radiology in newborn, 195
renal tract, 1015–1016, 1017f
imaging, 1015–1016, 1017f
SCTs, 900, 902
soft-tissue sarcoma, 932
ureteral duplication anomalies, 1073–1074, 1074f
vascular rings, 419
venous malformation, 858
Magnetic resonance urography (MRU), 1036, 1036f
prune belly syndrome, 817
Maintenance electrolyte therapy, 139t
Male genital anomalies, 1147–1151
circumcision and, 1147–1148, 1148f
embryology, 1147
penis, 1147
hypospadias, 1148–1149, 1148f
micropenis/buried penis, 1149
rare anomalies of testis, 1150–1151, 1151f
rare penile anomalies, 1149, 1149f
undescended testis, 1149–1150, 1150f
Males (boys)
anorectal anomalies, 684–687
imperforate anus without fistula, 687
management algorithm, 690–691, 691f
perineal fistula, 684, 685f
rectal atresia and stenosis, 687
rectourethral bulbar and rectourethral prostatic fistulas, 684, 685, 685f, 686f
rectovesical (bladder neck) fistula, 686–687, 687f
genital defects/anomalies
in CBE, 797, 799, 800–801, 801f
in cloacal exstrophy, 806, 807, 808, 809
in prune belly syndrome, 815
urethra
in prune belly syndrome, 815
Malformation
defined, 257
Malformations (congenital/developmental structural defects), 3–13
associated/additional
in CBD, 765
cloacal exstrophy, 806
in CPC, 704, 706–707
in MP, 624, 625t
in omphalocele and gastroschisis, 782–783
prune belly syndrome, 815–816
in tumors, 839
BA, *see* Biliary atresia (BA)
definition, 4
etiology, 4–5
liver
cysts and abscesses, *see* Hepatic cysts and abscesses
surgical correction of, 63–71

  laparoscopy, 793–794
  scintigraphy, 792
Meconium aspiration syndrome (MAS), 468
Meconium ileus
  clinical features, 619–620
  defined, 618
  differential diagnosis, 620–621
  HD and, 675
  histopathology, 619
  historical data, 618
  incidence, 618f
  medical/surgical treatment, 621–622
  pathogenesis, 618–619
  prenatal US and radiology, 620
Meconium passage with anorectal anomalies, 690, 691
Meconium peritonitis (MP), 624–629
  complications, 628–629
  etiology, 624, 625t
  management, 627–628
    operative, 628
    surgical, 628
  overview, 624, 625f, 625t
  pathology, 625–626, 625f, 626f
  symptomatology and diagnosis, 626–627, 626f, 627t
Meconium pseudocysts, 625, 626, 627
Mediastinal masses in newborn
  anesthetic management of infants, 396
  anterior mediastinum, 394, 394f
  differential diagnosis of, 392, 393f
  mediastinal neuroblastoma removal, 396–397, 397f
  middle mediastinum, 394–395, 395f
  posterior mediastinum, 395–396
  systematic approach to diagnosis of, 393–394
Mediastinal neuroblastoma removal, 396–397, 397f
Mediastinum
  lymphatic malformations, 890
Medical management
  for congenital hyperinsulinism (CHI), 593
  failure, neonatal ECMO and, 469–470
  meconium ileus, 621–622
  of neonates on ECMO, 473
Medical Research Council, 978
Medicine, nuclear, 193, 529–530
Medium-chain triglycerides (MCT), 435
  chylous ascites, 649–650
Medulla (oblongata) and fetal breathing, 21
Megacystis microcolon intestinal hypoperistalsis syndrome (MMIHS), 737–741
  characteristics, 737
  clinical presentation, 738–739
  etiology, 737
  histologic studies, 740, 740f
  occurrence, 738, 738t
  outcome, 740, 741
  overview, 737
  pathogenesis, 737–738, 738t
  prenatal diagnosis, 738, 738t
  prune belly syndrome and, 815
  radiological findings, 739, 739f
  surgical/autopsy findings, 739, 739f
Megaureter, 1064
  classification, 1064
Meige disease, 886
Meiosis, 249
Melanocytic nevi, congenital, *see* Congenital melanocytic nevi (CMN)
Melanosis, neurocutaneous, 865, 868–869
Membranous pyloric obstruction, 537, 538f, 538t
Mendelian single-gene-related syndromes, 837–838, 838t
Meningocele, 913, 914, 976, 977, 977t
  SCT *vs.*, 901–902
Mercaptoacetyltriglicine (MAG3), 1012
Mercaptoacetyltriglycine (MAG-3) scan
  prune belly syndrome, 817
Mesenchymal hamartoma of infancy, *see* Congenital mesoblastic nephroma (CMN)
Mesenchymal hamartoma of liver (MHL), 939–941
  clinical presentation, 940
  diagnosis, 940
  management, 940–941
  overview, 939
  pathology and pathogenesis, 939–940
Mesenchymal hamartomas (MHs), 772
Mesenchymal plate, post-hepatic, maldevelopment, 9
Mesenchyme, 7
Mesenteric and omental cysts, 642–646
  clinical characteristics, 643–644, 644t
  diagnosis, 644, 644f
  differential diagnosis, 644
  management, 644–646, 645f, 646f
  outcome, 646
  overview, 642, 643t
  spectrum and morphology, 642, 643f
Mesodermal nasal tumors, 912t
Mesothelial cysts, 642, 643f
Messenger RNA (mRNA)
  defined, 244
  protein synthesis from, 248f
Metabolic acidosis
  causes of, 142
  described, 142
Metabolic alkalosis
  causes of, 142
  described, 142
Metabolic disease(s), inherited (inborn errors of metabolism)
  tumors in, 838t
Metabolic responses
  preoperative assessment and, 107–108, 108t, 109t
Metabolic status
  preoperative assessment, 105–106
    acid–base balance, 105
    hyperbilirubinemia, 106
    hypocalcemia, 106
    hypoglycemia, 105–106, 105t

Penile agenesis, 1149
Penis (phallus)
in CBE, 795, 796, 797
surgery, 800–801
in cloacal exstrophy, 806, 809
surgery, 808
hypospadias, 1148–1149, 1148f
micropenis/buried penis, 1149
rare anomalies of, 1149, 1149f
Penrose drain, 664, 664f
Pentalogy of Cantrell, 383–4, 385f, 781, 783
Percutaneous cannulation, 184–185
Percutaneous core needle biopsy, 396
Percutaneous drainage, of systems with ureteroceles, 1096
Percutaneous endoscopic gastrostomy (PEG), 165–167, 166f
Percutaneous transhepatic cholangiography (PTC), 761
pyloric duplications, 635
Percutaneous umbilical blood sampling
prenatal diagnosis, 48
Percutaneous vesicoamniotic shunting or cystoscopic techniques, 1106
Perianal excoriation, HD and, 678
Perineal disease, 319
Perineal fistula, connecting rectum and, 690, 691, 692
definitive repair, 694, 695f
females, 687–688, 687f
male, 684, 685f
Perioperative management
fluid and electrolyte problems in neonates, 144
intraoperative management, 144–145
postoperative management, 145
Peripheral chemoreceptors and fetal breathing, 21, 22, 23
Peripheral intervenous central catheters (PICCs), 183
Peripherally inserted central catheter, 184
Peripheral nerve injuries
birth trauma, 76–78
brachial plexus injury, 76–77, 76f
facial nerve injury, 77, 77f
phrenic nerve injury, 77–78, 78f
Peripheral vein cut-down, 185–186
Peristalsis, 525
inefficient, in SBS
lengthening, 729–730, 730f
procedure interfering with, 731, 731f
tapering, 729–730, 730f
Peritoneal drainage
NEC, 656–657
SIP, 663–664, 663t, 664f
Peritonitis, MP, *see* Meconium peritonitis (MP)
Persistent cloaca, 689–690, 689f, 690f
Persistent hyperinsulinemic hyperglycemia of infancy (PHHI), 591

Persistent hypoglycemia, 595
Persistent omphalomesenteric duct, 791, 792f, 793f
Persistent pulmonary hypertension of newborn (PPHN), 105, 457, 468, 476
PHACES association, 850
PHACES syndrome, 384, 386
Pharmacological control of fetal breathing movements, 21–22
Pharyngeal hypotonia, 485
Phenotypic/anatomic DSD, 1134
PHH, *see* Posthemorrhagic hydrocephalus (PHH)
pH monitoring, twenty-four-hour, 528
Phosphatase and tensin homologue (PTEN)-associated with vascular anomaly, 860
Phosphodiesterase inhibitor (PDE), 459
Phototherapy, 139
Phrenic nerve injury, 77–78, 78f
Physical examination
  anorectal anomalies, 690
  CMN, 867, 868, 869f
  CPC, 704
Physiology
  of CO_2 insufflation, 282, 284, 285, 397, 1054, 1055
  perinatal, 17–23
Picibanil, 857, 887
PIE, *see* Pulmonary interstitial emphysema (PIE)
Pierre Robin sequence, 342–347
  airway management, 343–344
    distraction osteogenesis of the mandible, 343–344
    endotracheal tube, 343
    nasopharyngeal tube, 343
    noninvasive ventilation, 344
    tongue–lip adhesion/glossopexy, 343
    tongue positioning and stimulation plate, 344
    tracheostomy, 343
  cardiovascular anomalies, 346
  cleft palate, 345–346
  clinical features (new classification 2015), 343
  ear problems, 346
  etiology, 342
  genetics, 342–343
  incidence, 342–343

  pathology and pathogenesis, 660–661
  risk factors, 660
Spontaneous lower esophageal sphincter (LES) relaxation, 526–7
Spontaneous neonatal gastric perforation, 565
Spontaneous perforation of bile duct (SPBD), 650–651
Spontaneous transient LES relaxations (STLESR), 525
Staging (tumor)
  hepatoblastoma, 945, 945t, 946f, 946t
  neuroblastomas, 921–922, 922t, 923t
Stamm gastrostomy, 163–169, 163f–168f, 561; *see also* Gastrostomy
  laparoscopically assisted gastrostomies, 167–168
  laparoscopic-assisted percutaneous endoscopic approach, 168–169
  minimally invasive gastrostomies, 167
  percutaneous endoscopic gastrostomy, 165–167, 166f
Staphylococcus aureus, 206, 220, 316, 775
Staphylococcus spp., 661
Static renal scintigraphy, 1013–1014
Stem cell research, 301–307
  overview, 301
  scaffolds, 305–307
    cell-derived ECM scaffolds, 307
    natural acellular matrix, 306–307
    naturally derived materials, 305
    synthetic materials, 305–306
  stem cells, 301–305
    adult SCs, 304–305, 305f
    ES cells, 301–302
    fetal SCs, 303–304
    induced pluripotent SCs, 302–303
    somatic cell nuclear transfer (SCNT), 302
Stem cells therapy
  fetal surgery, 298
Stenosis, 687, 689
  bronchial, 408–9
  clinical appearance of, 598f
  jejunoileal atresia and, *see* Jejunoileal atresia and stenosis
  subglottic, 400–1, 400t, 401f
  tracheal, 404–6, 405f, 406f
  for tracheobronchial remnants, 507
Stenotic ureterocele, 1088
Stents
  choanal atresia, 340
  nasal, 340
  ureteral, 801, 808, 1040, 1062, 1063
Sterilization of skin/draping, 602–3
Sternal clefts, 385–6
Sternocleidomastoid tumor, 368–369; *see also* Torticollis
Steroids (corticosteroids)
  administration
    BA, 755
    hepatic hemangioma, 939
    for infantile hemangioma, 850, 852, 853–854
  congenital hemangioma, 855
  for NEC, 657
Steroids, DSDs and, 1133
Stillbirth, 43
Stomach (gastric) duplication, 634–635, 634t, 635f
Stomas
  in cloacal exstrophy, 177
  ileostomies, 177
  of large intestines, 174–178, 175f–178f
  mislocation, 174–176
  prolapse, 176
  retraction, 176
  of small intestines, 174–178, 175f–178f
  stenosis, 176
Stratification for risk of recurrence, neuroblastomas, 922, 924t
Streptococcus pyogenes, 367, 435, 887
Streptococcus thermophilus, 208
Stretta procedure, 531
Strictures
  anastomotic, 491, 499, 501, 522, 677
  esophageal, 316t, 318, 501, 517, 519, 1159, 1169
  NEC, 97, 657
  urethral, 705t, 1109, 1112, 1120
Stridor, defined, 398
Stridor in infants, 372–377, 373t, 375t
  glottic and subglottic disorders, 373–375
    glottic stenosis, 374
    subglottic stenosis, 374–375
    vocal fold immobility, 373–374
  overview, 372
  supraglottic disorders, 372–373
    laryngeal cysts, 373
    laryngomalacia, 372–373
  tracheal disorders, 375–377
    complete tracheal rings, 376–377
    tracheal atresia and agenesis, 377
    tracheomalacia, 375–376
    vascular anomalies, 376
Sturge–Weber syndrome, 855–856
Subarachnoid hemorrhage, 75
Subcutaneous emphysema, 566
Subcutaneous tissue
  newborn anatomy, 37–38
Subcutaneous VAD
  hydrocephalus and, 992
Subglottic disorders, 373–375
  glottic stenosis, 374
  subglottic stenosis, 374–375
  vocal fold immobility, 373–374
Subglottic hemangioma, 401–2, 402f
Subglottic stenosis (SGS), 374–375, 399, 400–401, 400t, 401f
Submucosal gas, 654, 654f
Submucosal injury, 519
Subserosal gas, 654, 654f
Substrate adhesion molecules (SAMs), 6
Succinylcholine, 118
Suction rectal biopsy (SRB), 674
Sudden infant death syndrome (SIDS), 530
Sugammadex, 119
Supraglottic disorders, 372–373
  laryngeal cysts, 373
  laryngomalacia, 372–373
Suprapubic catheter, 1068
Suprarenal glands
  genitourinary system in newborn, 34
Suprasternal cysts, 516–517
Supraumbilical approach
  intussusception, 717, 717f
  mesenteric and omental cysts, 645
Surfactant replacement
  acute respiratory distress syndrome and, 105
  congenital diaphragmatic hernia and, 105
  hypoxic respiratory failure, 129
  respiratory distress syndrome and, 105

Surgery
CBD, 763–767
choice of operative procedures, 763–764
complete excision, 764–765, 765f
mucosectomy/biliary reconstruction, 765–766, 766f
timing, 764
choanal atresia, 340
cloacal exstrophy, 807–808, 807t
CMN, 873–879
extremities, 878f, 879
face, 875, 875f
scalp, 874f, 875
trunk, 876–877, 876f, 877f
for congenital esophageal stenosis (CES), 510, 510f
findings, MMIHS, 739, 739f
hepatic infantile hemangiomas, 939
inguinal hernias, 724
for intestinal malrotation, 589–90
intussusception
check for pathological lead point, 717
closure, 717
indications for, 715, 716, 716t
manual reduction, 717, 717f
postoperative instructions, 717, 718
preparation for, 716
supraumbilical approach, 717, 717f
technique, 717–718
technique of resection, 717, 717f, 717t
liver transplantation, 327–328
lymphatic malformations, 888–890, 889f
macroglossia, 350–351
MP, 628
neuroblastomas, 923, 924–925, 925f, 926f
omphalocele and gastroschisis, 785–787, 785f, 786f, 787f
outcomes of HIV-infected children undergoing, 320
pediatric HIV infection and, 320
safety concerns specific to, 273–275
newborn surgery, 274–275
SCTs, 902–906, 903f, 904f, 905f

postoperative course, 1068–1069
prenatal diganosis and, 55
pressure-flow study, 1060
pyeloplasty, 1061–1064, 1061f
treatment, 1060–1061
PUJ obstruction, 1057
clinical presentation, 1058
diagnosis, 1058
prenatal diagnosis, 1057–1058
radionuclide scans, 1059–1060
ultrasound, 1058–1059, 1059f
surgical intervention, 70
ureterovesical junction obstruction, 1064
clinical features, 1064
diagnosis, 1065
endoscopic repair of ureter, 1068
intravenous urography, 1065
laparoscopic reimplantation, 1068
management, 1065
operation, 1065–1068, 1066f–1067f
prenatal diagnosis, 1064
renal scintigraphy, 1065
ultrasound, 1065
Ureter
duplication anomalies, *see* Ureteral duplication anomalies
endoscopic repair of, 1068
genitourinary system in newborn, 34
Ureteral duplication anomalies, 1072–1076
classification, 1072
clinical manifestation, 1073, 1073f
postnatal diagnosis, 1073–1074, 1074f
prenatal diagnosis, 1073
complete, 1072
embryology, 1072
incomplete, 1072
inverted Y, 1072
management, 1074–1076
ureteropelvic junction obstruction, 1076, 1076f
vesicoureteral reflux, 1074–1076, 1075f–1076f
overview, 1072
Ureterocele, 1040–1042, 1041f–1042f, 1073
cecoureterocele, 1089
ectopic, 1088
in newborn, 1088–1096
classification, 1088–1089, 1089f
clinical presentation, 1089, 1089f
conservative management, 1092
diagnosis, 1089–1090, 1090f, 1091f
duplex-system ureteroceles, 1092–1093
endoscopic puncture or incision, 1092, 1092f
excision or marsupialization, 1093
heminephroureterectomy, 1093–1095, 1095f
incidence, 1089
open procedure, 1095
operative procedure, 1093, 1093f, 1094f
overview, 1088
pathogenesis, 1088
percutaneous drainage, 1096
robot-assisted laparoscopic procedure, 1095–1096, 1096f
treatment, 1090–1096
ureteroureterostomy, 1095
orthotopic, 1088
sphincteric, 1088
sphincterostenotic, 1089
stenotic, 1088
Ureteropelvic junction (UPJ) obstruction, 1036–1038, 1037f
management, ureteral duplication and, 1076, 1076f
Ureteroureterostomy, 1095
Ureterovesical junction (UVJ), 1079
Ureterovesical junction (UVJ) obstruction, 1061, 1064
clinical features, 1064
diagnosis, 1065
endoscopic repair of ureter, 1068
intravenous urography, 1065
laparoscopic reimplantation, 1068
management, 1065
operation, 1065–1068, 1066f–1067f
Cohen's method, 1066–1068, 1067f
intravesical approach, 1065–1066, 1066f
prenatal diagnosis, 1064
renal scintigraphy, 1065
ultrasound, 1065
Ureters
in prune belly syndrome, 814, 814f
Urethra
CBE, 797
management, 799–800, 799f, 800–802, 801f–802f
fistulas connecting rectum and, 684, 685, 685f, 686f, 692, 694, 694f
definitive repair, 696–697, 696f, 697f, 698f
males
hypospadias, 12
prune belly syndrome, 815, 815f
Urethral atresia, 1030
Urethral/penile reconstruction, 1142
Urethral stricture; *see also* Strictures

PUVs and, 1112
Urgent tube thoracostomy, 437
Urinary ascites, 648–649, 649f
Urinary bladder
augmentation and procedures to increase outlet resistance, 1121–1122
secondary changes, PUVs and, 1101
Urinary catecholamines, 393, 394
Urinary diversion, after secondary transurethral ablation
temporary nephrostomy diversion on insertion of double-J stents, 1113
upper tract diversion, 1112–1113
vesicostomy, 1110–1112, 1121
Urinary incontinence
management after neural tube defects treatment and, 982
Urinary tract (renal tract)
anomalies, 738
CBE, associated with anomalies of, 797, 798
conjoined twins, surgery, 826
CPC associated with anomalies of, 705, 705t, 706, 707f
prune belly syndrome, 814
management, 817–818
VUD study, 817
upper, defects/anomalies/malformations
in CBE, 798
in cloacal exstrophy, 806, 808
Urinary tract infection (UTI), 1001–1008, 1029; *see also* Upper urinary tract obstructions
AAP imaging guidelines, 1007
breastfeeding and, 1003
clinical presentation, 1002, 1002t
diagnosis, 1003–1004
etiology, 1002
impact of circumcision, 1002–1003, 1003t
incidence, 1001
management, 1004–1006, 1005f
overview, 1001
prophylaxis, 1007, 1007t
surgical intervention, 1007–1008, 1007t
urological sequelae from, 1001
vesicoureteral reflux, 1006–1007; *see also* Vesicoureteral reflux (VUR)
